CHAPTER 79

Pneumothorax

Rodolfo A. Estrada
Jay I. Peters
Nilam J. Soni
Philip G. Ong

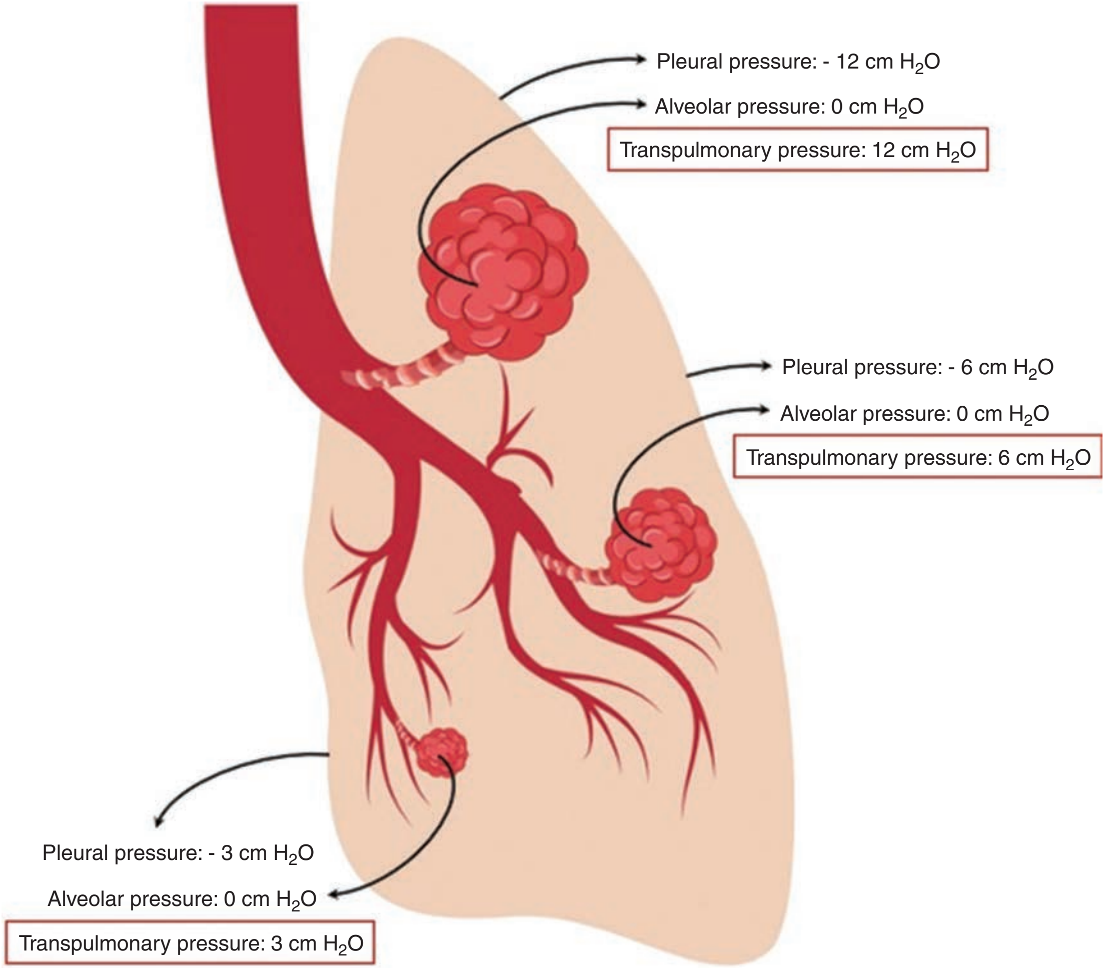
DEFINITION

The abnormal presence of air in the pleural cavity, separating the visceral from the parietal pleura, is known as *pneumothorax*. Traditionally, pneumothorax has been classified as having occurred spontaneously or as a result of trauma. Spontaneous pneumothorax can occur in a background of clinically normal lungs (primary spontaneous pneumothorax [PSP]) or in the setting of underlying lung disease (secondary spontaneous pneumothorax [SSP]). Since underlying anatomic lung abnormalities (subpleural blebs) are often identified in PSP,[1–3] it is now believed that the majority of PSPs occur in the setting of occult lung disease. Nevertheless, this method of classification is still common in practice.

Traumatic pneumothorax results from a disruption of the structural integrity of the lung, chest wall, esophagus, trachea, or bronchi secondary to either blunt or penetrating trauma to the chest. It can also occur as a consequence of diagnostic or therapeutic procedures such as central-line insertions, thoracentesis, or mechanical ventilation, in which case it is referred to as *iatrogenic pneumothorax*.

PATHOPHYSIOLOGY

As noted above, air does not normally exist within the pleural space. During both inspiration and expiration, the pressure within the pleural space is negative with respect to the alveolar pressure. This pressure gradient is called *transpulmonary pressure*, which results from the tendency of the lung to collapse (elastic recoil) and of the chest wall to expand. This negative pressure is not uniform throughout the pleural space, causing a greater distention of the alveoli at the apex of the lung secondary to higher negative pressure (Fig. 79-1). A gradient of 0.25 cm of water per centimeter of vertical distance can be measured between the apex and the base of the lung. The pleural pressure is also negative compared with the atmospheric pressure (760 mm Hg at sea level during end inspiration); nevertheless, the pressure gradient still favors net movement of alveolar air into the capillaries (average pressure of all gases in capillaries is 706 mm Hg) and not into the pleural space. Under normal circumstances, most individuals do not generate a net negative inspiratory force of −54 mm Hg.[4]



Pleural pressure: - 12 cm H_2O
Alveolar pressure: 0 cm H_2O
Transpulmonary pressure: 12 cm H_2O
Pleural pressure: - 6 cm H_2O
Alveolar pressure: 0 cm H_2O
Transpulmonary pressure: 6 cm H_2O
Pleural pressure: - 3 cm H_2O
Alveolar pressure: 0 cm H_2O
Transpulmonary pressure: 3 cm H_2O

Figure 79-1 Transpulmonary pressure changes related to lung zone.

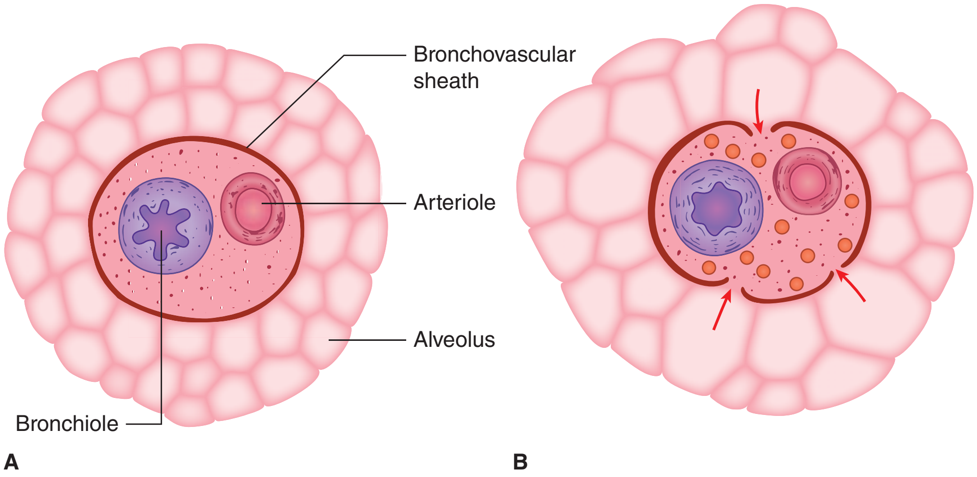


Figure 79-2 Proposed mechanism of alveolar rupture in spontaneous pneumothorax. **A.** Normal structures. **B.** Overdistention of marginal alveoli. Pressure in the adjacent bronchovascular sheath remains lower than in the overdistended alveoli. This pressure gradient may lead to rupture of the alveoli with dissection of air toward the pleura or mediastinum.

The presence of air in the pleural cavity is thought to occur by one of three events: a communication between the pleura and the alveolus, a communication between the atmosphere and the pleural space, or the presence of a gas-producing organism within the pleura.[4] When a communication develops between an alveolus and the pleural space, air will move from the alveolus into the pleural space until there is equalization of pressure or until the communication is sealed. The same happens with a communication between the chest wall and the pleural cavity. The greater the amount of air that enters the pleural cavity, the more the lung collapses. If unabated, enough air may enter the pleural space to cause a shift of the mediastinum and eventually lead to hemodynamic compromise, a condition referred to as *tension pneumothorax*.

Although the mechanism responsible for PSP is not completely understood, experimental overdistention of normal lungs results in rupture of subpleural alveoli.[5] Air can dissect along the bronchovascular sheath medially to produce pneumomediastinum, which may be accompanied by subcutaneous emphysema or pneumothorax (Fig. 79-2), or it can dissect to the peripheral portion of the lung.[6] Peripheral dissection of air may result in an air-containing space within or immediately beneath the visceral pleura. Pathologic studies of resected lungs from patients with PSP usually show one or both of these types of airspaces, a bleb or a bulla. A pneumothorax may occur when these peripheral bullae or blebs become distended and rupture into the pleural space.

The clinical impact of a pneumothorax depends on the degree of lung collapse, and the main physiologic consequences are a decrease in the vital capacity of the lung and a decrease in the Pa_{O_2}. The reduction in arterial Pa_{O_2} appears to be caused by low ventilation–perfusion ($\dot{V}/\dot{Q}$) ratios, absent ventilation (or anatomic shunts) and alveolar hypoventilation. Total lung capacity, functional residual capacity, and diffusing capacity are all also reduced, although less than vital capacity. Air in the pleural space causes a more uniform and therefore reduced regional lung ventilation by means of eliminating the gravitational gradients of pleural pressure. Lungs demonstrate airway closure at low lung volumes, which is the main cause of $\dot{V}/\dot{Q}$ imbalance in patients with pneumothorax.[7] If perfusion to the collapsed lung is preserved, there is an increase in pulmonary shunt and substantial hypoxemia. However, if perfusion to the collapsed lung is reduced by hypoxic vasoconstriction, hypoxemia may be minimal. In general, a pneumothorax occupying less than 25% of the hemithorax is not usually associated with significant shunt.[8] Hypoxemia tends to abate within 24 h under normal circumstances despite the degree of pneumothorax, presumably from redistribution of pulmonary blood flow.

In the healthy person, the decrease in vital capacity and Pa_{O_2} is typically well tolerated. In patients with compromised pulmonary function prior to pneumothorax, the decrease in vital capacity may result in respiratory failure with resultant hypoxemia and respiratory acidosis from alveolar hypoventilation. Upon evacuation of air from the pleural space, the Pa_{O_2} usually improves. In animal studies, the Pa_{O_2} returns to baseline immediately after re-expansion of the lung but in humans, normalization of the Pa_{O_2} takes longer and may occur over hours to several days; the delay in improvement may be related to the duration of the pneumothorax.[9]

REABSORPTION OF PLEURAL GASES

Between 1% and 6% of a pneumothorax is absorbed in 24 h with observation alone.[10] Gas reabsorption from the pleural space is achieved by simple diffusion from the pleural space into the venous blood and depends on four variables: (1) the pressure gradient for the gases between the pleural space in relation to the venous blood, (2) the diffusion properties for the gases present in the pleural space, (3) the area of contact between the pleural gas and the pleura, and (4) the permeability of the pleural surface (i.e., a thickened, fibrotic pleura will absorb less than normal pleura).

The solubility and diffusion properties of different gases vary considerably, and the speed of reabsorption will depend on the type of gas; nitrogen is the slowest gas to be reabsorbed, and carbon dioxide is the quickest along with water vapor. Tissue gas tensions are close to those of systemic venous blood: typically, $\text{pCO}_2 = 46$ mm Hg, $\text{pO}_2 = 40$ mm Hg, $\text{pH}_2\text{O} = 47$ mm Hg, and $\text{pN}_2 = 573$ mm Hg. Under normal circumstances, the gas pressure in the pneumothorax approximates that of the atmosphere, or 760 mm Hg, resulting in reabsorption via a positive pressure gradient toward the lung tissue with a capillary gas tension of 706 mm Hg. However, when breathing room air, this driving force is only 54 mm Hg (760–706 mm Hg) and this limits the rate of resorption. During inhalation of 100% oxygen, the partial pressure of nitrogen reduces from 573 to 0 mm Hg rendering a total gas pressure of 146 mm Hg. Although this is associated with an increase in oxygen in arterial blood, oxygen consumption in the tissues ensures that the partial pressure in the end-capillary blood rises only slightly (from 40 mm Hg to ~54 mm Hg). The results of small trials demonstrate that administration of high-flow oxygen expedites resolution of a pneumothorax.[11,12]

PRIMARY SPONTANEOUS PNEUMOTHORAX

PSP refers to development of a pneumothorax in the absence of underlying lung disease.

Epidemiology

The age-adjusted annual incidence of PSP ranges from 7.4 to 18 cases per 100,000 population in males and 1.2 to 6 cases per 100,000 in females. The male-to-female ratio ranges from 3:1 to as high as 6:1, and the peak incidence is in the third to fifth decade of life.[4,13]

Patients with PSP tend to be taller and thinner than control populations. A study of military recruits who developed spontaneous pneumothorax found subjects to be, on average, 2 inches taller and 25 lb lighter than the typical military recruit.[14] In another study, the frequency of PSP rose with increasing stature and reached an incidence of 200 per 100,000 person-years for subjects at least 76 inches tall.[13]

In addition to stature and male sex, tobacco smoking significantly increases the risk of spontaneous pneumothorax and has been associated with a ninefold or greater risk of developing a first PSP.[15] The relative risk of PSP has been shown to exhibit a dose–response relationship with the quantity of cigarettes per day and the length of exposure, increasing more than 20 times in men who smoke one-half pack per day and 100 times in men who smoke one pack per day compared to nonsmokers. The lifetime risk in healthy smoking men may be as high as 12%, as opposed to 0.1% in nonsmokers.[15] One review of 402 patients with PSP reported that 92% of the patients were smokers or ex-smokers.[8] Another study showed that patients who had stopped smoking more than 1 year before their first spontaneous pneumothorax had no recurrence during a follow-up of 5.2 years.[16]

Etiology

Although the diagnosis of PSP is restricted to patients without primary lung disease, it is likely that many of these patients do in fact have underlying lung pathology. Thus, a more accurate description of PSP is pneumothorax occurring in patients with no *obvious* lung disease.[17] While the exact mechanism by which a spontaneous communication between the alveolar space and the pleura has not been elucidated, most authors believe that rupture of a previously unidentified bleb or bulla adjacent to the pleura is to blame for the development of PSP.[18] These subpleural blebs and bullae are typically referred to as *emphysema-like changes (ELCs)* when seen on CT scan, and although it has been shown that the majority of patients with PSP have ELC, no causal relationship has clearly been established. These blebs are demonstrated by chest radiograph in only 20% of cases of PSP but can be seen in approximately 80% of affected patients by both CT imaging and by surgical evaluation.[19,20] In two studies, ELCs were found in 89% on the ipsilateral side and up to 80% bilaterally, while only 20% of those without PSP had these changes.[2,21] Another study showed that 81% of nonsmokers with healed PSP had ELCs, while those nonsmokers without PSP had none.[22] Despite this clear association, a causative relationship is still debated. In part, this is due to the observation that only a minority of blebs are observed to be ruptured at the time of surgery, and other lesions, termed *pleural porosity*, are observed.[4] Pleural porosity is believed to predispose the pleura to air leakage by disruption or replacement of the mesothelial cells of the visceral pleura with inflammatory cells that increase pleural permeability.[20]

The pathogenesis of these bullae, blebs, and pleural porosity is not definitively known but has been associated with a variety of elements, most commonly with airway inflammation.[23,24] Airway inflammation secondary to cigarette smoking may be associated with or contribute to the development of these blebs. Respiratory bronchiolitis in smokers may be an important element in the development of PSP.[25] Pathologic evidence of respiratory bronchiolitis was found in more than 88% of smokers undergoing surgery for PSP.[26]

In addition to airway inflammation, other factors have been linked to ELC and pleural porosity, including connective tissue abnormalities, hereditary influences, increased negative pressure at the apices associated with ectomorphic body habitus, anatomic bronchial abnormalities, and overdistention of alveoli with poor collateral ventilation. Pleural pressure is most negative at the apices, and the degree of negativity relates to the height of the lungs. The alveoli of taller persons are subjected to greater mean distending pressures. Over a long period, this phenomenon could lead to the formation of subpleural blebs in a taller population genetically predisposed to bleb formation.

There are multiple reports of genetic associations or patterns of PSP. Some reports suggest that PSP is inherited through an autosomal dominant gene with variable penetrance,[27] while others report an associated autosomal recessive[28] or X-linked recessive inheritance pattern.[27] Genetic risk factors that have been associated with PSP include the HLA haplotype A_2B_{40},[29] the α_1-antitrypsin phenotypes M_1M_2, and the FBN1 gene mutations.[30] Gene mutations have been found in both sporadic and familial cases of PSP. Familial spontaneous pneumothorax (FSP) occurs in family clusters and accounts for 12% of PSP cases; a significant subset of these patients have mutations in the *FLCN* gene.[27,31] Recurrence rates of FSP are difficult to compare with sporadic pneumothorax given the different study methodologies, but they are thought to be higher regardless (~70% in FSP vs. 33% in sporadic).[32] This supports a lower threshold for surgical intervention after the first pneumothorax if known family history is present.[33–38] A genetic approach to management is not addressed by current guidelines but should be routinely implemented in suspected FSP cases.[32] Further workup (i.e., detailed history/physical exam, CT chest, genetic testing, and referral to a genetic specialist) should be pursued when key features of FSP are noted, such as isolated family history of PSP, family history of bleb/cyst/bullae, and personal history of non-apical bleb/cyst/bullae. The importance of diagnosing FSP goes beyond PSP to include patient surveillance of other syndromic pathologies and family screening protocols.

The rate of recurrence after a PSP is approximately 33% (range, 23%–52%), and recurrence usually occurs within 1 to 2 years after the first episode.[39] The rate of recurrence may increase with each successive pneumothorax. In one study, the risk of recurrence increased to more than 60% after the second pneumothorax and to 83% after the third.[40] Although there is no predilection for the right or left hemithorax with the initial episode, more than 75% of recurrences occur on the same side as the first pneumothorax. Despite the documentation that pleural blebs occur bilaterally in many patients with PSP, the risk of contralateral pneumothorax is only 5% to 10%. Risk factors for recurrence that have been identified include greater height, lower weight, and smoking status.[41] Death rarely occurs after PSP.[42] In a study of spontaneous pneumothorax in which patient ages ranged from 15 to 34 years (most likely representing patients with PSP), the mortality rate was reported to be 0.09% for men and 0.06% for women.[43]

SECONDARY SPONTANEOUS PNEUMOTHORAX

SSP is a more serious event than PSP because, by definition, the patient has underlying lung disease. A pneumothorax in a patient with already diminished pulmonary reserve can be life-threatening and requires more immediate medical attention and intervention.

Epidemiology

The incidence of SSP is similar to that of PSP. An epidemiologic study in Olmsted County, Minnesota documented an incidence of

TABLE 79-1 Etiology of Secondary Spontaneous Pneumothorax

Obstructive Lung Disease
Chronic obstructive pulmonary disease (COPD)
Asthma
Interstitial Lung Disease
Idiopathic pulmonary fibrosis (usual interstitial pneumonitis [UIP])
Nonspecific interstitial pneumonitis
Langerhans cell histiocytosis
Lymphangioleiomyomatosis
Sarcoidosis
Radiation pneumonitis or fibrosis
Infection
P. jiroveci pneumonia
Tuberculosis
Coccidioidomycosis
Acute bacterial pneumonia (i.e., *Staphylococcus*)
Malignancy
Primary lung carcinoma
Pulmonary metastasis (especially sarcomas)
Complications of chemotherapy
Connective Tissue Disease
Rheumatoid arthritis
Ankylosing spondylitis
Marfan syndrome
Ehlers–Danlos syndrome
Polymyositis/dermatomyositis
Scleroderma
Other
Catamenial pneumothorax
Pulmonary infarction
Pulmonary alveolar proteinosis
von Recklinghausen disease
Granulomatosis with polyangiitis (Wegener)

SSP of 6.3/100,000 year for males and 2/100,000 year for females.[13] On average, patients with SSP are 15 to 20 years older than patients with PSP due largely to the older age of patients with emphysematous lung disease. The risk of recurrence for SSP is somewhat higher than for PSP and ranges from 40% to 80%, again likely due to the underlying lung pathology. Although airway diseases (chronic obstructive pulmonary disease [COPD], cystic fibrosis [CF], and severe asthma) are the most common underlying lung disorders, a wide spectrum of pulmonary diseases has been associated with SSP (Table 79-1).[44]

COPD

COPD is the most common cause of SSP. The Veterans Administration Cooperative Study on Pneumothorax noted that pneumothorax tended to occur in patients with moderately severe COPD, with one-quarter of the participants having an FEV_1 below 1 L and a mean FEV_1/FVC ratio of 57%.[45] Persistent bronchopleural fistula was also noted to be common in patients with obstructive lung disease, and 35% of patients had an air leak for more than 5 days. In another series of more than 500 patients with SSP, COPD was the etiology in 69%, primary or metastatic tumor in 18%, granulomatous disease (sarcoid and tuberculosis) in 7%, and other pulmonary infections in 3%.[46] In contrast to the low mortality rate associated with PSP, patients with SSP have a much higher risk of death. The VA Cooperative study reported an analysis of three papers that, combined, revealed a mortality of 16% for SSP.[45] Another study[47] showed that SSP increased the mortality of age-matched COPD patients 3.5-fold.

Cystic Fibrosis

Pneumothorax is a common and potentially serious complication of CF lung disease. It occurs more frequently in CF than in the general population and results in significant morbidity and mortality, typically occurring with more advanced disease.[48–50] Approximately 3.5% of patients with CF will suffer this complication at some point in their lives. The majority occur in adulthood, with a median age of 21 years.[51] Pneumothorax may also be a marker of poor prognosis, with one study showing the median survival after the first spontaneous pneumothorax to be only 29.9 months.[52]

The pathophysiology of spontaneous pneumothorax in CF is likely related to chronic airway inflammation that eventually leads to structural changes with severe airflow obstruction, inflammation with poor clearance of thick and inspissated secretions, air trapping in the distal airways, and eventual rupture of the pleural surface with rising alveolar pressures.[51]

The risk of developing pneumothorax increases with age and with declining pulmonary function (FEV_1). One study of pneumothorax in CF demonstrated that the risk of pneumothorax increased by 50% when FEV_1 was <30% predicted.[50] Other important risk factors for the development of pneumothorax include the presence of *Pseudomonas aeruginosa*, *Burkholderia cepacia*, or *Aspergillus* in the airways, the use of dornase alfa, and the use of noninvasive mechanical ventilation. The presence of these airway pathogens may increase inflammation and secretions leading to obstruction, and the use of inhaled dornase alfa may cause bronchospasm leading to acute decline in FEV_1 with inhalation.[53]

CF-specific recommendations exist regarding the management of pneumothorax.[49] A full discussion of these is beyond the scope of this chapter, but several points regarding airway clearance in the setting of pneumothorax are of particular importance. With small pneumothoraces it is recommended that most airway clearance modalities be continued, with the exception of those providing positive-pressure or percussive ventilation, which could further increase the size of pneumothorax. With large pneumothorax, it is recommended that airway clearance modalities be held.[49,54] Although the use of inhaled medications could provoke coughing, it is not recommended that these be held.

Recurrence of pneumothorax is more frequent in this population. An estimated failure rate of 37% with initial tube thoracostomy alone has been reported, but up to 70% of all patients have an overall failure rate with tube thoracostomy (i.e., initial failure plus ipsilateral recurrence) ultimately needing more definitive treatment.[55] Despite the recurrence rate being so high, the guidelines recommend reserving pleurodesis for large recurrent pneumothoraces.[49] However, because the recurrence rate in CF is high, many CF centers still consider pleurodesis after the first episode. In the past, there was concern that pleurodesis would preclude patients from lung transplantation. However, recent studies have shown that pleurodesis does not add appreciably to complications during lung transplantation.[56,57] Although center-dependent, pleurodesis is no longer considered a contraindication to transplantation.[56]

Catamenial Pneumothorax

Catamenial pneumothorax is an uncommon condition that occurs in women and is defined as recurrent pneumothoraces occurring

72 hours before or after the onset of menses. One study reported a mean of 3.17 episodes (range, 2–10) in a population of women prior to surgical treatment.[58] This syndrome, by definition, occurs during the reproductive years, usually in the third or fourth decade of life; however, cases associated with hormone replacement have been reported.[59] Although initially felt to be extremely rare, the condition is becoming increasingly recognized. A series from the Mayo Clinic found the condition in 5.6% of women with spontaneous pneumothorax over a 21-year period; however, more recent studies suggest the incidence of this disorder may fluctuate between 18% and 33% in women of reproductive age with recurrent spontaneous pneumothorax.[60,61]

There is no single, definitive etiology for the development of catamenial pneumothorax. One hypothesis suggests pleural and/or diaphragmatic endometriosis as the basis for this disorder, but less than one-third of women are found to have endometrial deposits at the time of surgical exploration.[61] Alternative mechanisms that have been proposed include peritoneal air entering the thoracic cavity through diaphragmatic defects during menstruation, endometrial implants in the terminal bronchioles causing obstruction, and increased circulating levels of prostaglandin $F_2\alpha$ during menstruation causing bronchospasm and vasospasm that leads to alveolar rupture.[59] It is possible that various pathogenic mechanisms are involved.

The diagnosis, as mentioned above, is based on *recurrent* pneumothorax occurring at or around the time of menstrual flow. Onset is typically heralded by chest pain and dyspnea. Over 90% of catamenial pneumothoraces affect the right hemithorax, but isolated left-side or bilateral pneumothoraces have been reported. Catamenial pneumothoraces are usually mild or moderate but can rarely be life-threatening.

Given the unacceptably high recurrence rate of 50% to 100% with medical treatment alone, management with surgery followed by medical/hormonal therapy is typically indicated.[59,62,63] Surgical treatment, which can be accomplished with video-assisted thoracoscopy, involves excision of endometrial implants, closure of any diaphragmatic defects, stapling of any blebs, and pleurodesis. Medical treatment is aimed at suppressing the ectopic endometrium and ovulation and at preventing further seeding. This is typically accomplished by using oral contraceptives, danazol, or gonadotropin-releasing hormone agonists. No controlled trials have examined the efficacy of one medication over another. If menses is not suppressed, there is a risk of recurrence, even after surgical treatment. Hysterectomy with bilateral oophorectomy will induce surgical menopause and has been employed to prevent pneumothorax.[59]

Pneumothorax in Acquired Immunodeficiency Syndrome

Patients with acquired immunodeficiency syndrome (AIDS) have a significantly increased risk of developing pneumothorax. Roughly 2% of AIDS patients experience spontaneous pneumothorax. In one study, pneumothorax complicated 1.2% of 599 HIV patient admissions over 3 years.[64] Mortality was significantly higher (30.8%) in patients with pneumothorax than in those without (5.8%).

Pneumothorax in AIDS patients is associated with multiple infectious and noninfectious etiologies. *Pneumocystis jiroveci*, bacterial infections, Kaposi sarcoma, cytomegalovirus, pulmonary *Cryptococcus*, coccidiomycosis, and mycobacterial disease have all been associated with spontaneous pneumothoraces. Other risk factors for the development of pneumothorax in HIV include tobacco use, treatment with inhaled pentamidine, and the presence of a pneumatocele on chest radiograph. With the introduction of highly active antiretroviral therapy (HAART), HIV has become a chronic disease; as HIV-infected patients age, they are at increased risk of pulmonary diseases including COPD, lung cancer, interstitial lung disease, and cancer. Each of these disorders increases HIV patients' susceptibility to SSP.[65]

Most studies have shown *Pneumocystis jiroveci* pneumonia (PCP/PJP) to be the primary etiology. However, an observational study of 105 HIV patients with spontaneous pneumothoraces found bacterial pneumonia to be the major underlying etiology (34.3%) followed by PCP (29.5%) and pulmonary tuberculosis (15.2%).[66] In addition, the authors noted that bacterial pneumonia was a more common cause among drug users and those with CD4+ count greater than 200 cells/mL, whereas PCP was a more common cause among patients with sexually transmitted HIV and CD4+ counts less than 200 cells/mL. Given the strong association with PCP, evaluation and treatment for PCP is recommended in any patient with AIDS who presents with an otherwise unexplained spontaneous pneumothorax.

The high frequency of pneumothoraces seen in patients with PCP is thought to be secondary to the presence of subpleural cysts and subpleural necrosis associated with this entity. Extensive tissue invasion within the alveolar interstitium is common in severe PCP and may result in subpleural necrosis. These cystic changes are thought to be due to repeated episodes of inflammation and cytotoxic effects of HIV on pulmonary macrophages with elastase production and necrosis of lung tissue.[56,67] These lesions occur most frequently at the apices of the lungs and consist of necrotic alveoli filled with *P. jiroveci* organisms, macrophages, eosinophilic exudate, and fibrinous material.[68] Because of the necrotizing nature of the pneumonia, spontaneous pneumothorax from PCP is notoriously difficult to treat. Persistent air leaks often require tube thoracostomy for several weeks, and up to one-quarter of patients require surgical intervention. Patients with advanced AIDS are often discharged with Heimlich valves.[69] Some authors recommend early thoracoscopic therapy in good surgical candidates to avoid prolonged hospitalization. Therefore, if surgical intervention is planned, some authors recommend preoperative CT scan of the chest and median sternotomy in patients with significant bilateral disease to facilitate bilateral pleurodesis.[70]

Pulmonary tuberculosis (TB) is still a significant problem in patients with HIV. Pneumothorax has been reported in approximately 7% of HIV patients with pulmonary TB.[71] All pneumothoraces associated with TB should be treated and often require prolonged periods of chest tube drainage. In cases of TB, it has been suggested that thoracotomy should not be considered until the patient has received antituberculosis therapy for at least 6 weeks; however, objective evidence that this affects outcome is lacking.

TRAUMATIC PNEUMOTHORAX

Trauma is the most common cause of pneumothorax, which is a potentially life-threatening injury. Traumatic pneumothoraces are present in around 20% of patients who have undergone either polytrauma or trauma to the thorax.[72] Noniatrogenic traumatic pneumothorax can result from either penetrating or nonpenetrating chest injury. Computed tomography is routine in the evaluation of both blunt trauma and penetrating trauma in the emergency department and often identifies an "occult pneumothorax" (seen on CT scan but not on initial chest radiographs). While current guidelines recommend chest tube placement for traumatic pneumothoraces, especially in patients receiving positive-pressure ventilation, this area remains controversial. Recent studies suggest the majority of occult pneumothoraces in stable patients can be managed conservatively even in the setting of positive-pressure ventilation.[72,73]

Penetrating chest trauma produces a pneumothorax by allowing air to enter the pleural cavity directly through the chest wall. In addition, if the visceral pleural is penetrated, air may leak from the tracheobronchial tree. If the continuity of the chest wall is disrupted, an open pneumothorax is produced. If the opening in the chest wall is larger than the diameter of the trachea (1.0–2.1 cm in an adult), air movement occurs through the pathway of least resistance, and air is preferentially inspired into the thoracic cavity through the open chest wound. Any open chest wound must be occluded to assure adequate ventilation of the patient.

Pneumothorax is also a frequent finding in patients with blunt trauma to the chest. The visceral pleura may be lacerated secondary to a rib fracture or dislocation; however, in almost one-half of patients with pneumothorax secondary to blunt trauma, there are no associated rib fractures. This is especially common with blunt trauma to the chest secondary to blast injuries and high-altitude falls into water. In such incidents, the abrupt increase in the pressure gradient between the alveolus and the adjacent bronchovascular sheath causes disruption of the alveolar membrane. Dissection of air through the interstitial space results in either pneumothorax or pneumomediastinum.

Occasionally, patients with traumatic pneumothorax have coexisting injuries of the tracheobronchial tree or esophagus. In a patient with a traumatic pneumothorax, fiberoptic bronchoscopy should be performed in the presence of hemoptysis or a persistent air leak. Eighty percent of injuries to the tracheobronchial tree are within 2.5 cm of the carina, most commonly on the right side at the membranous–cartilaginous interface. The main lobar bronchi and the cervical trachea are the next most common sites of injury.

Traumatic rupture of the esophagus usually produces a hydropneumothorax. Therefore, if a patient with a traumatic pneumothorax also has a pleural effusion, the possibility of esophageal rupture should be entertained. Almost all patients with perforation of the thoracic esophagus also have dysphagia and pneumomediastinum. An elevated pleural fluid amylase concentration is a reliable screening procedure for esophageal rupture. Once the diagnosis is suspected, contrast radiographic studies of the esophagus should be performed as soon as possible. Untreated, esophageal rupture results in mediastinitis and septic shock; therefore, a high index of suspicion is essential in making an early diagnosis.

IATROGENIC PNEUMOTHORAX

Increasing utilization of invasive diagnostic and therapeutic interventions has significantly increased the rate of iatrogenic pneumothorax. These cases may result in considerable morbidity, prolonged hospitalization, and even death, for the affected patient.[74] Iatrogenic pneumothorax can occur as a complication of multiple procedures, but the leading cause of iatrogenic pneumothorax is transthoracic needle aspiration followed by subclavian vein catheter insertion, thoracentesis, transbronchial biopsy, pleural biopsy, and positive-pressure ventilation.[75] The incidence ranges between 17% and 26% with transthoracic needle aspiration; risk factors include COPD, depth of lesion within the lung, and lesions smaller than 2 cm.[76–78] Pneumothorax may also occur with transbronchial needle aspiration, liver biopsy, intercostal nerve block, mediastinoscopy, and tracheostomy among others.

Central venous catheterization carries the second highest risk of iatrogenic pneumothorax. The reported risk ranges from 2% to 12% (most studies <3%) when using anatomic landmarks for guidance. Subclavian catheterization carries a higher risk than internal jugular catheterization. The increasing use of real-time sonographic guidance for central venous catheterization has significantly decreased this risk for both internal jugular and subclavian approaches.[79,80] Similarly, the routine use of real-time ultrasound guidance for localization of needle puncture site during thoracentesis may decrease the risk of pneumothorax, which develops in approximately 5% of cases[81] (Table 79-2).

Mechanical ventilation is a frequent, potentially lethal cause of iatrogenic pneumothorax. The overall incidence of pneumothorax during mechanical ventilation ranges from 4% to 15% but may be significantly higher in patients with underlying inflammatory diseases such as aspiration pneumonia.[82] The incidence of pneumothorax is also increased during mechanical ventilation if patients have chronic pulmonary disease, are on increased amounts of positive end-expiratory pressure, or have right mainstem intubation.[82] The incidence of pneumothorax has been reported to be 6.9% to 14% of patients with acute respiratory distress syndrome (ARDS).[83,84] Another study reported a 48.8% incidence of pneumothorax in patients with severe ARDS requiring extracorporeal support.[85]

TABLE 79-2 Iatrogenic Pneumothorax Rate of Common Procedures

Procedure	Pneumothorax Rate
Flexible bronchoscopy (any procedure)	0.10%–0.16%[168]
Thoracentesis	6%[169]
Transbronchial biopsy (TBB)	1%–6%[168]
Transbronchial cryobiopsy (TBCB)	4.8%–20%[170]
Transbronchial needle aspiration (TBNA)	1%–6%[171]
Endobronchial ultrasound (EBUS)-TBNA	0.2%[172]
Central line insertion	<0.2%[173]
• Internal jugular vein	<0.1%[173]
• Internal jugular vein, ultrasound guided	0.45–3.1%[173]
• Subclavian vein	
Mechanical ventilation	4–15%[174]
CT-guided percutaneous fine needle aspiration	17–26.6%[175]
Navigational bronchoscopy	4.3%[176]
Percutaneous nephrolithotomy	7%[177]
Percutaneous liver biopsy	0.8%[178]

A pneumothorax should be suspected in any patient whose clinical status acutely decompensates on the ventilator. Bedside clues include a sudden increase in respiratory rate or appearance of patient–ventilator dyssynchrony. An increase in the peak and plateau pressures on the ventilator can be a sensitive indicator if the patient is on volume-cycled ventilation. The peak inspiratory pressure often rises suddenly as the lung compliance falls. If the patient is on pressure control ventilation, decreased tidal volumes will be a sign of pneumothorax.

Radiographs of critically ill, mechanically ventilated patients are frequently obtained only in the supine or semi-supine position. In one study, supine and semierect radiographs were obtained in 88 critically ill patients with 112 cases of pneumothorax.[86] The radiologist initially failed to detect the pneumothorax in 30% of the cases. Patients with extensive infiltrates, such as in the setting of ARDS, may have no suggestion of lung collapse on chest radiograph. In these patients, the only radiologic sign that may be evident is that of a deep sulcus on the side of the pneumothorax. This finding, as well as any increased lucency on a supine film, should raise suspicion of a pneumothorax and be evaluated by either erect or decubitus views, or ultrasound. If erect or decubitus films cannot be obtained or ultrasound is unavailable, CT scans of the chest may be necessary.

It should be noted that recipients of bilateral lung transplants and patients who have had a "clamshell" thoracotomy do not have an intact mediastinum. Because of this, the normally separate pleural spaces may be in direct communication with each other. Physicians performing procedures on these patients need to be aware that the patient can develop bilateral pneumothoraces because of this anomaly.[87]

CLINICAL FEATURES

The main symptoms with the development of a pneumothorax are chest pain and dyspnea, which occur in 95% of patients. The pain is usually acute, localized to the side of the pneumothorax, and typically pleuritic. Cough, hemoptysis, orthopnea, and Horner syndrome are uncommon manifestations of a pneumothorax.[8,88] A small percentage of patients are asymptomatic or complain only of generalized malaise and fatigue.

Spontaneous pneumothorax usually occurs at rest, and fewer than 10% occur during strenuous exercise. In PSP, both the dyspnea and chest pain may subsequently abate over the first 24 h. This may explain why nearly half of patients have symptoms for 2 days before seeking medical attention and why 18% wait for more than a week.[8] Most patients with SSP have more severe symptoms than patients with PSP, and dyspnea frequently seems out of proportion to the size of the pneumothorax.[89] Patients with SSP often present in respiratory distress with significant tachycardia and tachypnea. Patients with tension pneumothorax, most commonly seen in the setting of mechanical ventilation or after cardiopulmonary resuscitation, often progress to profuse diaphoresis, marked hypoxemia, cyanosis, respiratory acidosis, and hypotension.

Small pneumothoraces (<20%) are usually not detectable on physical examination. In patients with COPD, even larger pneumothoraces may be difficult to detect since decreased breath sounds and hyperresonance may already be present.[90] On physical examination, vital signs are usually normal, with the exception of moderate tachycardia and to a lesser degree tachypnea. Examination of the chest may reveal the affected side to be larger and move less during respiration. Tactile fremitus is absent, the percussion note is hyperresonant, and breath sounds are absent or reduced on the side with the pneumothorax.

In patients with PSP, arterial blood gases often show hypoxemia and hypocarbia from hyperventilation. Hypoxemia is usually mild when less than 25% of the lung is affected. When more than 25% of the lung is involved, pulmonary shunts occur more frequently and hypoxemia may be severe. In patients with SSP, pulmonary reserve is already diminished and life-threatening hypoxemia and hypercapnia may be present. In one study, the mean pO_2 was 48 mm Hg and the mean pCO_2 was 58 mm Hg when patients with emphysema presented with a spontaneous pneumothorax.[90]

Patients with a left pneumothorax may show changes on ECG suggesting an anterolateral myocardial infarction. A rightward shift of the frontal QRS axis and clockwise rotation of the heart result in a diminution of precordial R-wave voltage, a decrease in the QRS amplitude, and precordial T-wave inversion.[91] These electrocardiographic features differ from a transmural myocardial infarction because of the absence of ST-segment elevation or significant Q waves. An anterior subendocardial infarction may present with T-wave inversion but without the rightward shift in the frontal axis. The electrocardiographic changes with a left pneumothorax may normalize when the patient is in the upright or right lateral decubitus position.

RADIOGRAPHIC APPEARANCE

Below are considered the radiographic (plain radiography and CT) and ultrasound findings in pneumothorax.

Plain Radiography

Classically, the diagnosis of pneumothorax is established by demonstrating the outer margin of the visceral pleura (and lung) separated from the parietal pleura (and chest wall) by a lucent space devoid of pulmonary vessels (Fig. 79-3) on the chest radiograph. The pleural line may be difficult to detect with a small pneumothorax unless high-quality upright films are obtained. In erect patients, pleural gas collects over the apex, and the space between the lung and chest wall is most notable there. In the supine position, gas migrates along the broad ventral surface of the lung, making detection on a frontal radiograph difficult. In the supine position, the juxtacardiac area, the lateral chest wall, and the subpulmonic region are the best areas to search for evidence of pneumothorax. Several studies have shown that expiratory films have little or no advantage over upright inspiratory films in the diagnosis of pneumothorax.[92–94] Data from the Trauma Audit and Research Network (TARN) noted that 48% of subjects presenting to the emergency department after trauma had "occult pneumothoraces" missed on plain chest radiographs.[72]

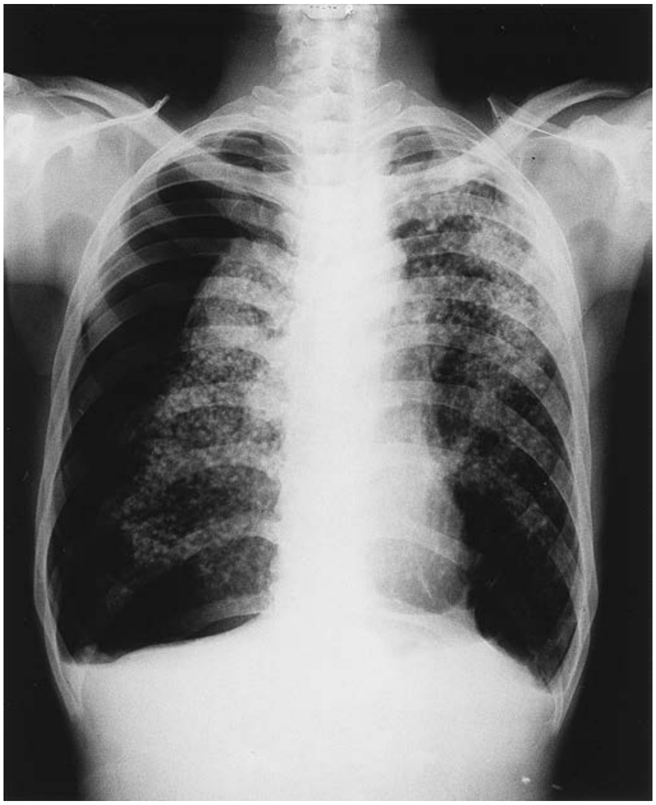

Figure 79-3 A patient with nodular silicosis and a spontaneous secondary pneumothorax. The visceral pleural line is clearly seen with the absence of vascular workings beyond the pleural line. There are cicatricial bullae in both bases.

It is very important to differentiate the pleural line of a pneumothorax on chest radiographs from that of a skinfold, clothing, tubing, or chest wall artifact. Careful inspection of the film may show that the artifact extends beyond the thorax, or that lung markings are visible beyond the apparent pleural line. In the absence of underlying lung disease, the pleural line of a pneumothorax usually parallels the shape of the chest wall. Artifactual densities generally do not parallel the course of the chest wall over their entire length. Avascular bullae or thin-walled cysts can be mistaken for a pneumothorax. The pleural line caused by a pneumothorax is usually convex at its center toward the lateral chest wall. As opposed to a pneumothorax, the inner margins of bullae or cysts are, in general, concave rather than convex towards the chest wall and do not exactly conform to the contour of the costophrenic sulcus. A pneumothorax with a pleural adhesion may also simulate bullae or lung cysts. An adhesion tends to form a straight line connecting the lung to the parietal pleura; bullae or cysts have rounded edges. Such features are not 100% specific, and if there is any doubt as to whether the patient has a bulla or cyst or a pneumothorax, a CT scan should be obtained as CT can usually differentiate the two.[95] Pleural effusions may occur coincident with pneumothorax in up to 20% to 25% of cases. Hemopneumothorax occurs in 2% to 3% of cases of spontaneous pneumothorax. Bleeding is believed to represent rupture or tearing of vascular adhesions between the visceral and parietal pleura as the lung collapses.

Quantification of the size of a pneumothorax on chest radiographs is helpful, but the methods for quantifying lack uniformity and are by no means precise. Light suggested measuring the average diameters of the collapsed lung and of the affected hemithorax, then cubing these diameters to estimate the percentage of collapsed lung by the following equation: $100 \times (1 - \text{diameter of collapsed lung}^3/\text{diameter of hemithorax}^3)$.[88] For example, if the diameter of the collapsed lung is 6 cm and the diameter of the hemithorax is 10 cm, the collapsed lung is estimated by the formula $100 \times (1 - 6^3/10^3)$. Thus, the estimated size of the pneumothorax is 78%.[88] Rhea et al.[96] proposed the use of a nomogram to calculate the size of the pneumothorax. With this method, the average intrapleural distance is calculated by measuring the interpleural distance at the apex and at the midpoints of both the upper and lower lungs. These three values are then averaged, and the number is reported on a nomogram, which gives an estimated size of the pneumothorax (Fig. 79-4).

The most common radiographic manifestations of tension pneumothorax are mediastinal shift, diaphragmatic depression, and rib cage expansion (Fig. 79-5). Any significant degree of displacement of the mediastinum from the midline position on maximum inspiration, or any depression of the diaphragm, should be taken as evidence of tension. The degree of lung collapse is an unreliable sign for or against the presence of a tension pneumothorax since underlying lung disease may prevent collapse even in the presence of tension.

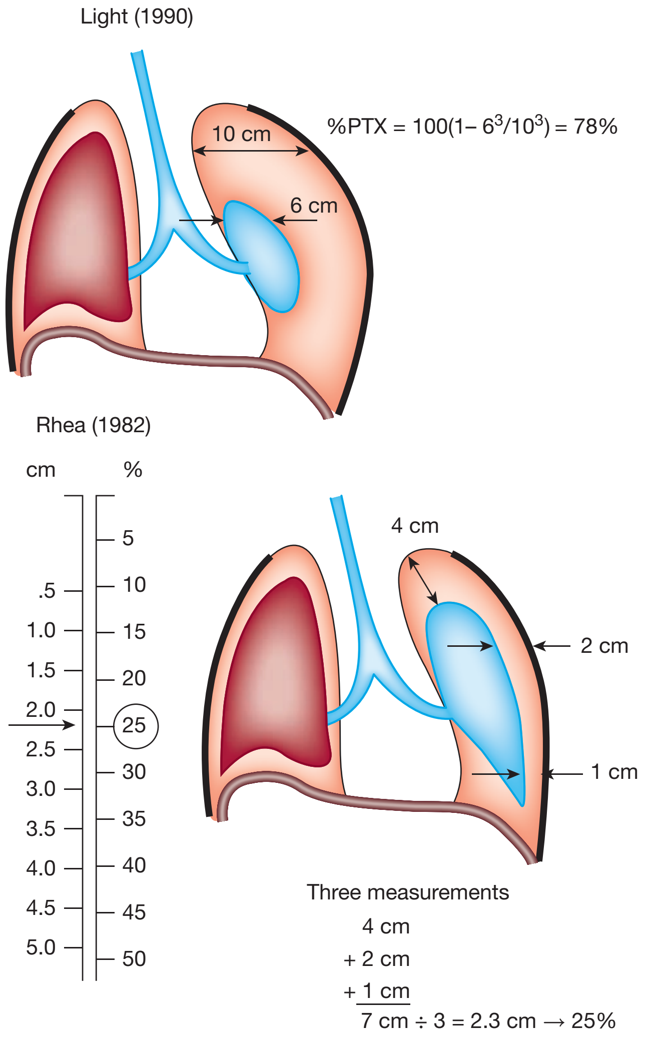

Figure 79-4 Estimation of the size of the pneumothorax according to the method described by Light[89] and Rhea et al.[97] *(Reproduced with permission from Pearson FG, Deslauriers J: Thoracic Surgery. Philadelphia, PA: Churchill Livingstone; 1995.)*

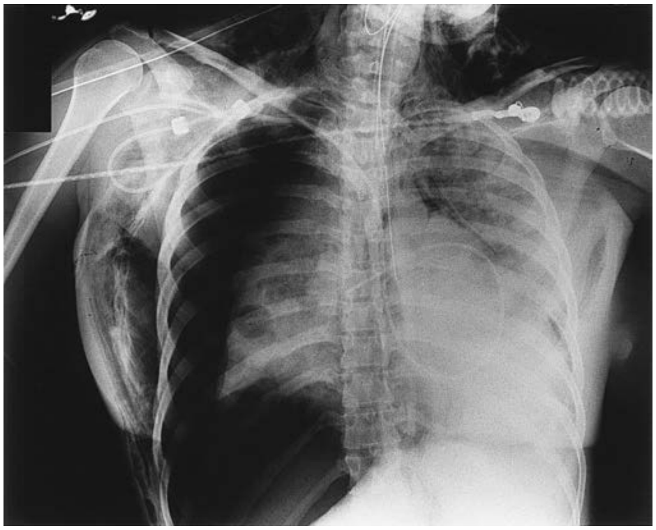

Figure 79-5 Right tension pneumothorax in a young patient with staphylococcal endocarditis and septic emboli. There is marked depression of the right hemidiaphragm, shift of the mediastinum, and subcutaneous emphysema. Note that the pulmonary artery catheter, endotracheal tube, and nasogastric tube (midchest) are all displaced to the left.

■ Computed Tomography

CT scans of the chest are being used with increasing frequency in patients with pneumothorax. CT scans may be necessary to diagnose pneumothorax in assessment of trauma patients in the emergency room and in critically ill patients when upright or decubitus chest radiographs are not possible. CT scans may also prove helpful in predicting the risk of recurrence in patients with spontaneous pneumothorax. One study demonstrated that patients who have larger or more numerous blebs on chest CT scans are more likely to have recurrence.[97] CT scans also have the ability to assess the volumetric size of a pneumothorax and can accurately assess changes over time.[98]

Traumatic pneumothoraces, if large, can be detected both clinically and with chest radiography. However, a small, posttraumatic pneumothorax may be easily missed by both physical examination and chest radiograph. One prospective series revealed that 51% of trauma patients presented with an occult pneumothorax that was not seen on initial chest radiograph, but identified on CT imaging.[99] In another large series looking at multiple trauma patients, 4.4% had a pneumothorax and 38.8% of these were detected only by CT scan.[100] Of note, recent studies suggest that traumatic pneumothoraces measuring 35 mm or less on CT scans can be managed conservatively in more than 90% of cases.[73] Early incorporation of a routine CT scan in all patients with chest trauma or multiple traumatic injuries may be required to successfully diagnose traumatic pneumothoraces.

■ Lung Ultrasound

Ultrasound has evolved to become an indispensable bedside tool for rapid diagnosis of pneumothorax.[100–103] Since the early 1990s, our understanding of lung and pleural ultrasonography has continued to mature as new research has emerged and more clinicians

Video 79-1 Normal lung sliding. This sagittal view using two-dimensional ultrasound shows normal lung sliding through an anterior chest interspace. Two ribs that cast shadows are seen on the left and right edges of the image. The pleural surface is seen below the ribs. The visceral and parietal pleura are apposed giving a shimmering, glistening appearance as the visceral pleura slides back and forth against the parietal pleura with respirations. *Video available on AccessMedicine.com.*

Video 79-2 Absence of lung sliding due to pneumothorax. Using two-dimensional ultrasound in a sagittal plane, the absence of lung sliding can be appreciated as the shimmering, glistening appearance of the pleura is not seen below the ribs. *Video available on AccessMedicine.com.*

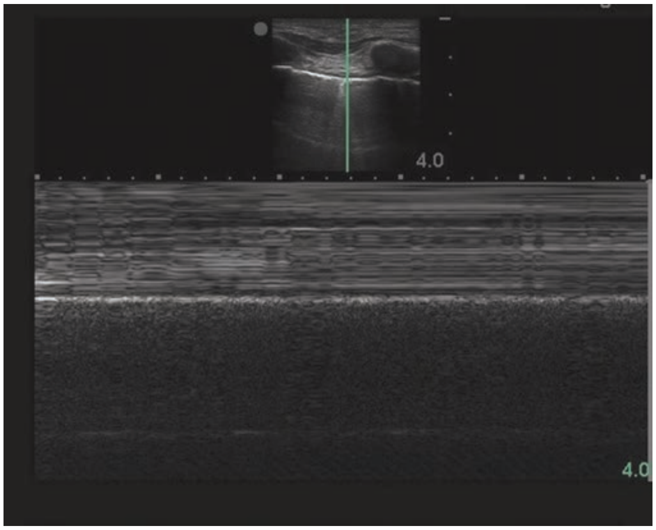

Figure 79-6 Normal lung in M-mode. A two-dimensional ultrasound image at the top shows the sample line along which the movement of all tissues is recorded and displayed below. The chest wall creates a series of horizontal lines. Also noted are the hyperechoic line of the pleura and a granular pattern created by aerated lung.

have integrated point-of-care ultrasound into clinical practice (see Chapter 29).

Lung ultrasound is more sensitive than chest x-ray for detection of pneumothorax when using chest CT as the gold standard. Early studies established superiority of lung ultrasound compared with chest x-ray to detect pneumothorax, with sensitivities and specificities ranging from 66% to 100% and 91% to 100%, respectively.[104–107] Meta-analyses report pooled sensitivities of 79% to 95% and specificities of 98% to 99% for lung ultrasound in detecting pneumothorax. In contrast, pooled sensitivity and specificity for chest radiography have been reported at 40% to 52% and 99% to 100%, respectively.[108–110]

Normal lung and pleura are characterized by two ultrasound findings: lung sliding and A-lines. By conventional two-dimensional ultrasonography, normal visceral and parietal pleura appear as a bright white (hyperechoic) line that glistens with respirations as the visceral pleura slides back and forth against the parietal pleura (Video 79-1). A principal finding to diagnose pneumothorax is absence of lung sliding (Video 79-2). The presence of air in between the visceral and parietal pleura in pneumothorax prevents propagation of ultrasound waves beyond the parietal pleura, and the sliding, shimmering appearance created by apposed pleura is not seen.[111,112] Presence of lung sliding definitively rules out pneumothorax with a negative predictive value of 100%.[104] However, absence of lung sliding is not specific to pneumothorax and can be seen with any cause of pleural symphysis (chemical pleurodesis, infectious/inflammatory adhesions, fibrosis) or lung volume loss (mainstem intubation, massive atelectasis, mucus plug, pneumonectomy, apnea).[111] If lung sliding is absent, identification of the lung point, a specific sign of pneumothorax, can confirm the diagnosis. The lung point is the edge of a pneumothorax, or boundary between collapsed and aerated lung, and a lung point is 100% specific to rule in pneumothorax.[107] The defining feature of a lung point is visualization of aerated lung sliding into the field of view next to collapsed lung (Videos 79-3 and 79-4). It is essential to avoid mistaking the edge of lung along the heart border or diaphragm for a lung point. In a supine patient, the lung point can be found anteriorly when the pneumothorax is small, and laterally when it is large.[112]

Evaluation of lung sliding can be confirmed using M-mode, or motion mode. M-mode displays movement of tissues over time. The normal M-mode pattern of lungs includes horizontal, linear lines at the top, corresponding to the chest wall; a hyperechoic line corresponding to the pleura; and a granular pattern at the bottom corresponding to aerated lung parenchyma. The normal M-mode pattern is called "seashore" sign with the aerated lung parenchyma representing the beach and the chest wall representing the ocean (Fig. 79-6). In pneumothorax, the granular pattern of aerated lung parenchyma is lost, and horizontal, linear lines are seen throughout the display. The M-mode pattern of pneumothorax is often referred to as a "stratosphere" or "barcode" sign (Fig. 79-7).[111] The lung point

Video 79-3 Lung point sign (lateral chest wall). The edge of a pneumothorax, or lung point, can be seen on the curvature of the lateral chest of a mechanically ventilated patient with a large, postprocedural pneumothorax. Aerated lung superiorly *(left)* slides into the field of view next to the collapsed, nonsliding portion of lung *(right)*. *Video available on AccessMedicine.com.*

Video 79-4 Lung point sign (anterior chest wall). The edge of a pneumothorax, or lung point, can be seen on the anterior, inferior chest wall of a patient with a small, spontaneous pneumothorax. Aerated lung slides in and out of the field of view next to the collapsed, nonsliding portion of lung. *Video available on AccessMedicine.com.*

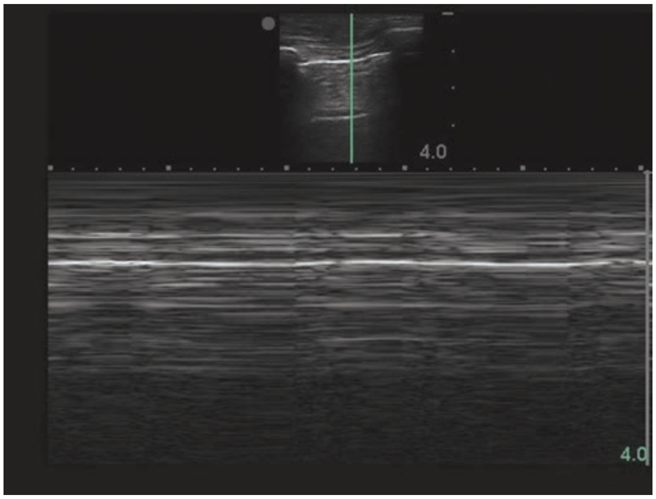

Figure 79-7 Pneumothorax in M-mode. The separation of visceral and parietal pleura by air from a pneumothorax prevents ultrasound waves from reaching the visceral pleura resulting in loss of the granular pattern of normal lung at the bottom of the M-mode image. A series of horizontal lines is seen throughout the M-mode image and is often called "stratosphere sign" or "bar code sign."

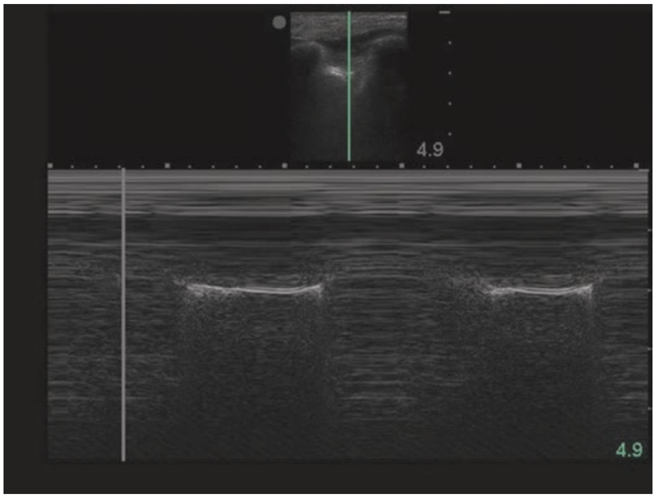

Figure 79-8 Lung point in M-mode. This M-mode image displays alternating patterns of normal lung and pneumothorax as normal, aerated lung slides over the area of collapsed lung.

will display a distinct M-mode pattern with alternating segments of "seashore" and "barcode" pattern (Fig. 79-8).

A-lines are ultrasound image artifacts due to repeated reflections, or reverberations, between the highly reflective pleura and transducer. A-lines are seen as a series of equidistant horizontal white lines deep to the pleura (Fig. 79-9). A-lines are seen in normal lungs but also in pneumothorax, pulmonary embolism, COPD, or asthma due to reverberations between the parietal pleura alone and transducer. Therefore, presence of A-lines supports a diagnosis of pneumothorax but is not specific for pneumothorax. In contrast, the presence of B-lines, an artifact arising from the pleura, rules out pneumothorax with a negative predictive value of 100% (Video 79-5).[106] In the absence of lung sliding, visualization of B-lines or other vertical artifacts called comet-tails rules out pneumothorax (Video 79-6).

A focused lung ultrasound examination to evaluate for pneumothorax can be performed rapidly—in less than 1 min in one study by experienced clinicians.[107] A phased-array, linear-array, or microconvex transducer is most often used. Specifically, for evaluation of pneumothorax, a high-frequency (5–10 MHz), linear-array transducer is preferred because of its higher resolution and sensitivity (82% vs. 76%) compared with convex-array transducers.[110] Air in the pleural space accumulates in the least dependent parts of the chest, which are anterior and inferior in supine patients. The anterior chest wall is scanned by placing the transducer in the midclavicular line at the level of the clavicle with the transducer orientation marker pointed cephalad. The transducer is then slid inferiorly to the diaphragm, evaluating each intercostal space sequentially for lung sliding. If absence of lung sliding is detected, the transducer is moved laterally in search of the lung point to confirm presence of a pneumothorax and to qualitatively assess the size of the pneumothorax. M-mode may be used to confirm the presence or absence of lung sliding.[112] The lateral and posterior chest walls should be interrogated subsequently, although most pneumothoraces will be detected on the anterior chest wall in supine patients unless the pneumothorax is loculated.

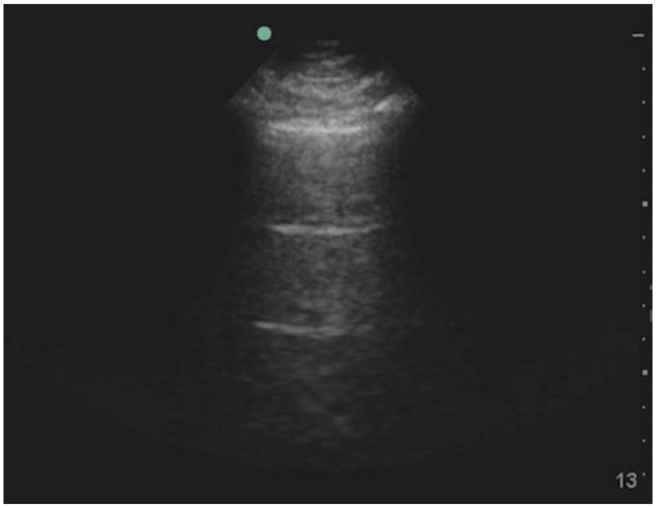

Figure 79-9 A-lines. A-lines are a type of reverberation artifact seen as equidistant horizontal lines that are generated from reflections of the pleura. A-lines are seen in normal, aerated lungs, but are also seen in pneumothorax, pulmonary embolism, chronic obstructive pulmonary disease, and asthma.

Video 79-5 B-lines. B-lines are a type of reverberation artifact, also known as comet-tail artifacts, that arise from the pleural surface and extend vertically to the bottom of the screen as discrete, hyperechoic rays that slide with pleural movement. Presence of B-lines rules out pneumothorax. *Video available on AccessMedicine.com.*

Video 79-6 B-lines and absence of lung sliding. Although lung sliding is absent in this patient with pneumonia, visualization of B-lines confirms apposition of the visceral and parietal pleura ruling out pneumothorax. *Video available on AccessMedicine.com.*

Given the difficulties associated with diagnosing small pneumothoraces by plain chest radiograph, as well as the cost and delay of CT scans, thoracic ultrasound is quickly emerging as a valuable tool for the diagnosis of occult pneumothorax. The small size and portability of newer machines, as well as the advantage of immediate bedside interpretation, make ultrasound especially helpful in the management of critically ill and hemodynamically unstable patients. Most data have come from trauma literature where ultrasound has a more well-established role. Hand-held ultrasonography was shown to have better sensitivity (48.8 vs. 20.9%) and similar specificity compared with chest radiograph for detection of traumatic pneumothorax using CT as the gold standard.[113] A review of ultrasound specifically in ICU patients concluded that ultrasound had a sensitivity of 95% and specificity of 94% compared with CT for the detection of pneumothorax.[114] Ultrasound has the additional advantage of serving as a guide to direct the site of drainage.[115]

MANAGEMENT

The American College of Chest Physicians (ACCP)[116] and the British Thoracic Society (BTS)[3] have published society guidelines for the management of spontaneous pneumothorax; unfortunately, these guidelines have not been updated since 2001 and 2010, respectively. In 2015, the European Respiratory Society (ERS) published a task force statement on PSP.[117] However, all three guidelines are somewhat outdated and fail to capture significant recent studies on the treatment options for pneumothorax. There is considerable heterogeneity and deviation from guideline-based management,[118] probably reflecting the lack of randomized trials and the disparities in the recommendations from various society guidelines.

Therapy for pneumothorax is dependent on the size of the pneumothorax, symptomatology, and etiology. The basic tenets of therapy are to evacuate the space, achieve closure of the leak, and either prevent or reduce the risk of recurrence. A variety of treatment methods and adjuncts exist. The choice of therapy depends on many factors, including the clinical status of the patient, the cause of the pneumothorax, evidence for concomitant lung disease, prior history of pneumothorax, risk of recurrence, and, finally, the experience and preferred techniques of the physicians caring for the patient as well as the availability of specific therapeutic options.[119] Major categories of treatment methods are listed below, followed by suggested guidelines for their application.

■ Observation

Simple observation of the patient with a pneumothorax requires evidence that the air leak is sealed (i.e., that there is no further progression of the pneumothorax). Conservative management of pneumothoraces is not a new concept. In 1966, Stradling and Poole[120] reported the safety and efficacy of conservative management and the low risk in patients with PSP. Recently a large, multicenter, randomized trial[121] was performed in patients with moderate to large PSP (≥32% on chest radiography using the Collins equation), where the conservative group was observed for at least 4 h in the emergency department. Chest tube drainage was performed if symptoms persisted despite analgesia or if the patient became physiologically unstable with or without enlarging pneumothorax on repeat chest radiograph. In the conservative group, 84.6% did not undergo interventions. Lung re-expansion at 8 weeks was noninferior in the conservative group compared with the intervention group (94.4% vs. 98.5%). This form of management is generally reserved for patients with PSP since pulmonary reserve is reduced in most patients with SSP.

■ Aspiration

Aspiration of pneumothorax has been advocated by some but has shown varied levels of success, and there is poor consensus between guidelines as to which patients warrant this approach.[122] Most studies on aspiration have been performed in patients with PSP. A meta-analysis of randomized controlled trials of simple aspiration versus chest tube insertion concluded that simple aspiration was advantageous because of shorter hospitalization times and no significant difference in recurrence rates at 1 year.[123] In these studies, approximately 66% of patients had resolution of their pneumothorax. A more recent meta-analysis of all hemodynamically stable adults with spontaneous pneumothorax compared needle aspiration versus small-bore chest tube (<14 French) versus larger-bore chest tube and found no statistical differences between the various forms of therapy.[124] However, patients with secondary or a recurrence of spontaneous pneumothorax generally do not have good results with simple aspiration.[122,125–127]

■ Tube Thoracostomy

This entails the placement of an indwelling catheter into the pleural space for continual removal of the intrapleural gas. For uncomplicated pneumothorax without evidence of significant amounts of fluid or blood, one may use small thoracostomy tubes (pig-tail catheters) ranging from 8 to 14 French to minimize the discomfort of a larger tube in the intercostal space. Generally, a safe site for a chest tube or pleural catheter placement is the lateral chest wall above the fourth to sixth ribs in the mid- to anterior axillary line. For small pneumothoraces, an anterior midclavicular chest tube can be placed in the second or third intercostal space. Large-bore chest tubes have essentially been replaced by the insertion of pig-tail catheters placed under ultrasound. The main indications to place a large-bore chest tube are hemothorax and selective cases of small pneumothorax in patients on mechanical ventilation where the risk of injuring the lung is deemed too high to place a catheter by needle insertion.[128]

Following insertion, the tube is then connected to a pleural drainage system. Commercial systems commonly employ variations on the three-chamber system (Fig. 79-10). The three-chamber system

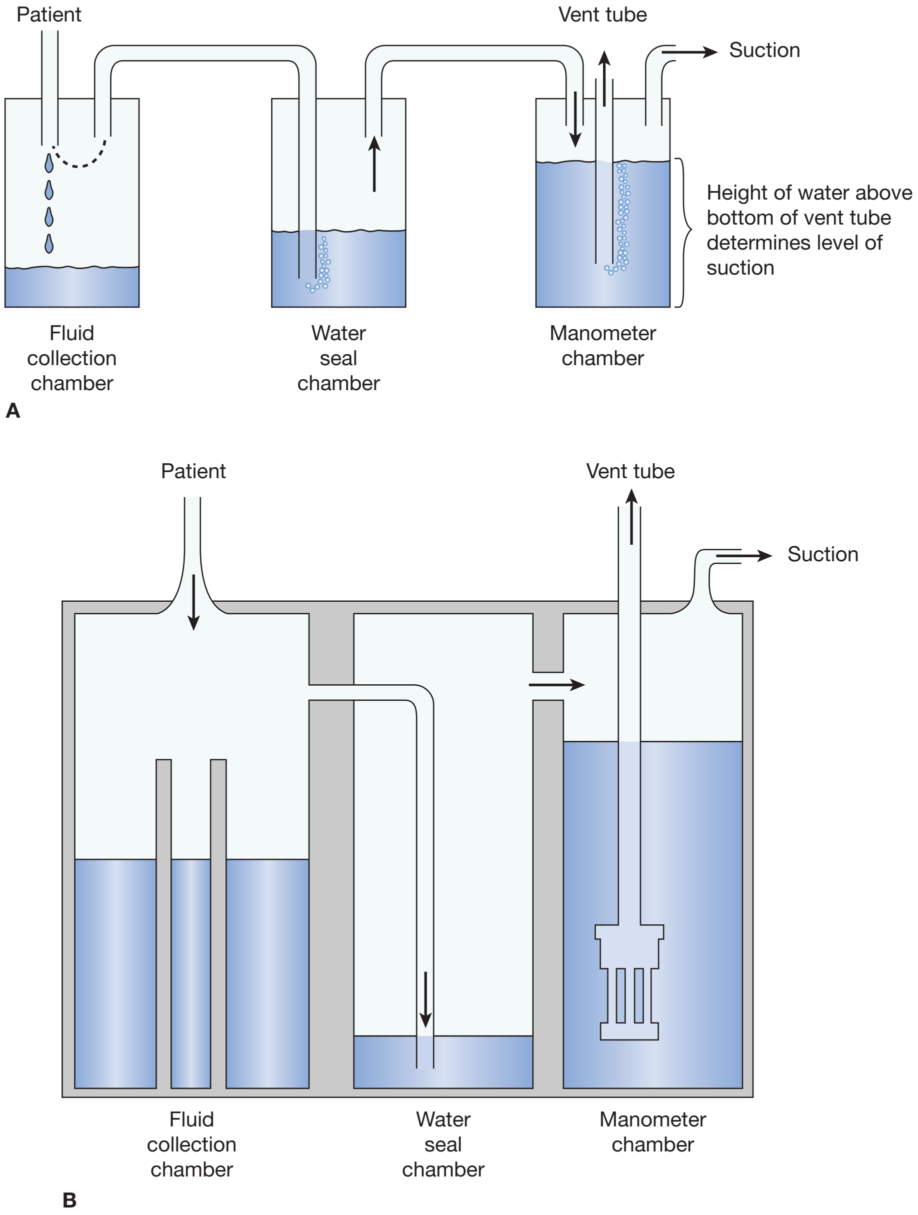

Figure 79-10 **A.** Three-bottle chest tube drainage system. The system consists of a collection bottle, a water-seal bottle, and a suction-control bottle. The collection bottle allows sterile drainage from the pleural spaces. The water-seal bottle acts as a one-way valve in the absence of suction, and the suction bottle allows for the regulation of negative pressure applied to the pleural space. **B.** Commercially available, compartmentalized plastic drainage system.

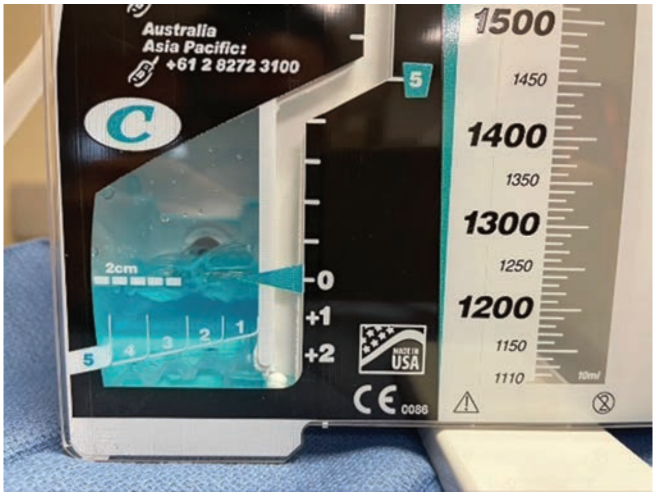

Figure 79-11 A dry suction chest tube drain system showing the appearance of air bubbles from left to right in the air leak monitor, which signifies an active air leak. The air leak monitor is graded from 1 (low) to 5 (high) to allow for monitoring the extent of the air leak.

consists of a fluid collection chamber attached to a water seal chamber to allow egress of gas from the pleural space, but in a one-way fashion. The final connection is to a manometer bottle, which regulates the degree of suction being applied to the system. (Newer "dry vac" systems use a resistor rather than water to regulate the amount of negative pressure [Figs. 79-11 and 79-12].) After placement of the tube, care should be taken with regard to immediate placement to suction because of the potential for re-expansion pulmonary edema (REPE). In many cases it may be prudent to leave the tube to water seal and allow the lung to expand gradually. Once the majority of the pneumothorax is evacuated, suction is applied for the next 24 h. If an air leak exists, as evidenced by continual or intermittent egress of gas through the water seal chamber, suction is maintained (Table 79-3). Once there is no evidence of an active air leak, the tube may be placed to water seal. After an additional period of observation of 12 to 24 h, the chest tube may be removed if the pneumothorax does not recur.[129] Tube thoracostomy alone will result in closure of an air leak in most cases by complete evacuation of the pleural space and apposition of the visceral and parietal pleura. Persistence of an air leak for more than 72 to 96 h generally presages a leak that will not close by this regimen and should prompt consideration of more aggressive therapy.[130]

TABLE 79-3 Cerfolio Classification of Air Leaks

During forced expiration only, usually asking the patient to cough	Grade 1, (FE) forced expiration
Expiratory only	Grade 2, (E) expiration
Inspiratory only	Grade 3, (I) inspiration
The air leak chamber shows continuous bubbling during both inspiration and expiration, which correspond to large leaks usually	Grade 4, (C) continuous

Data from Cerfolio RJ. Advances in thoracostomy tube management. Surg Clin North Am. 2002;82(4):833–848.

Potential problems with small catheters relate to a greater propensity for blockage of the tube. Also, the smaller size makes them more prone to kinking, clotting from blood or fluid, and sealing of the side- and end-ports of the tube by the lung. Flushing pig-tail catheters is often required to assure they remain functional and to clear blood or fluid.

A variation on the use of pleural drainage systems is the substitution of a one-way valve to permit early discharge from the emergency department or hospital with subsequent ambulatory management of the patient.[131] The most common is the Heimlich flutter valve, which is particularly useful in cases in which there is a protracted air leak but surgical therapy is declined or not possible. This valve is not widely recommended, however, owing to a potential for problems with blockage, which may not be immediately recognized on an outpatient basis. A recent, open-label, randomized study compared a self-contained device with a drainage chamber and internal Heimlich valve (Rocket Pleural Vent) and demonstrated statistically fewer days of hospitalization but a higher incidence of serious adverse events related to the procedure.[132]

Pleurodesis

Pleurodesis is an adjunct to the other forms of therapy. The goal is to achieve pleural symphysis, or adhesion of the visceral and

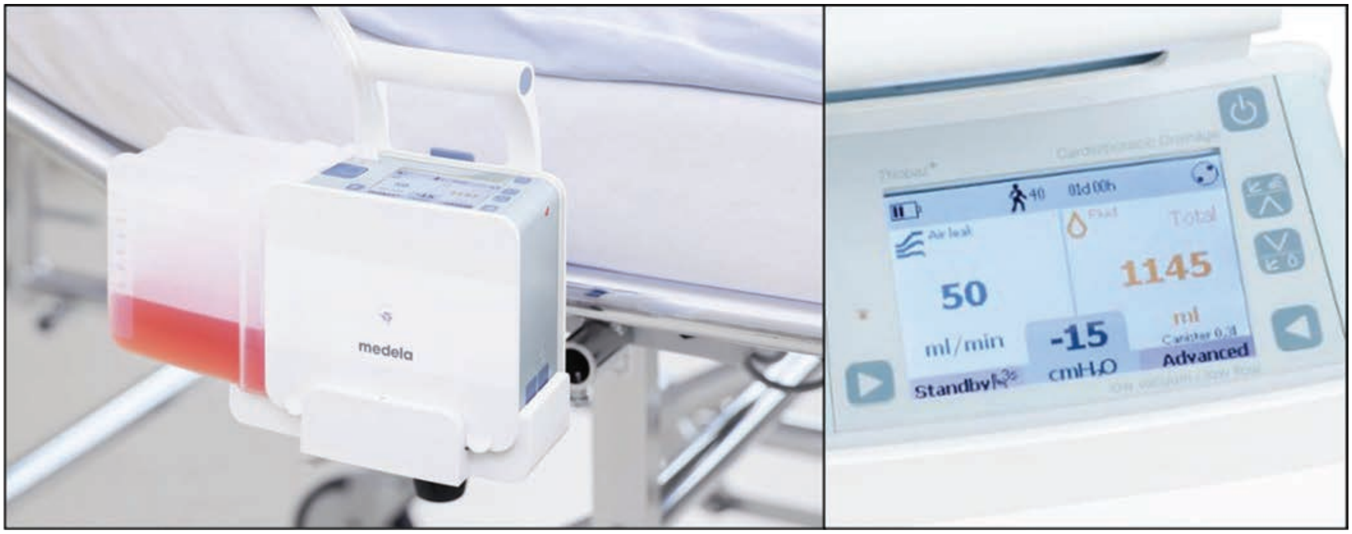

Figure 79-12 Thopaz digital chest drainage and monitoring system. (©2022 Medela.)

parietal pleura to obliterate the pleural space. Sealing the visceral and parietal pleura together will prevent future air leaks and prohibit the lung from "falling away" from the chest wall. The basic mechanism entails chemical or physical irritation of the pleural surface to promote an inflammatory response and subsequent adhesion formation.

The goal of pleurodesis is to prevent recurrence in both PSP and SSP. There is good consensus for the use of pleurodesis in both; however, the timing and approach remain somewhat controversial.

Chemical pleurodesis may be used in combination with tube thoracostomy or surgical therapy. In patients who are unable to undergo a surgical procedure (e.g., due to severe comorbidity), pleurodesis can be achieved by administering the sclerosing agent through a chest tube. The success rates of pleurodesis utilizing antibiotics (doxycycline, minocycline) or talc by slurry have been shown to be superior to chest tube drainage alone.[16]

As an adjunct to tube thoracostomy, the chemical of choice is suspended in fluid and instilled through the tube. The tube is clamped for 1 to 2 h, then placed back to either suction or water seal. Periodically changing patient position during this pleurodesis has not been shown to improve outcome with tetracycline derivatives.[133,134] Success is largely dependent on apposition of the visceral and parietal pleura during the period of inflammation while the tube is clamped. Excessive pleural fluid will dilute the sclerosing agent, and an air leak will allow the lung to separate from the chest wall. Doxycycline pleurodesis in the face of an air leak has been successful in safely closing the air leak;[135–137] however, all agents have significantly reduced success rate with a persistent air leak present.

The ideal agent should be effective, safe, easy to administer, widely available, and affordable. A number of pleural irritants have been suggested, including talc, antibiotics (minocycline and doxycycline), quinacrine, silver nitrate, bleomycin, and autologous blood. Side effects of pleurodesis with a sclerosing agent include chest pain (variable in severity), dyspnea, and fever that occasionally persists for over a week.[138]

Tetracycline was shown to be very effective in creating sufficient pleural fibrosis formation when compared with hydrochloric acid, quinacrine, nitrogen mustard, bleomycin, or sodium hydroxide.[5] A randomized study comparing the recurrence rates in PSP after drainage alone with that of drainage plus tetracycline or talc found recurrence rates of 36%, 13%, and 8%, respectively.[136] Tetracycline, however, is no longer commercially available. Minocycline and doxycycline have replaced tetracycline, with experimental and clinical data suggesting equal efficacy.[116,139–141] Typical doses of these antibiotics are 0.5 to 1 g of doxycycline in 50 to 100 mL normal saline and 600 mg of minocycline in 50 to 100 mL of normal saline.

Talc has also been shown to be a very effective sclerosing agent when applied as slurry via a chest tube or by talc poudrage during thoracoscopy.[142,143] The choice between talc slurry (via chest tube) or talc insufflation (thoracoscopic) usually depends on the medical circumstance and the ability of the patient to tolerate single lung ventilation. In an experimental study, talc was noted to be as efficacious as mechanical abrasion.[144] In a meta-analysis, talc achieved a success rate of 91%.[145] Doses of 3 to 5 grams of graded-sterile talc in 100 to 200 mL of normal saline are felt to be optimal for talc slurry. The potential drawbacks of talc slurry include prolonged pleural drainage and inhomogeneity of deposition. The distribution of talc may lead to loculation and incomplete symphysis. The advantage is that it can be performed easily at the bedside. There are data, however, that suggest an increased incidence of acute respiratory failure and systemic complications associated with the use of talc as a sclerosant. The size of the talc particles (<15 μm) and the dose (>5 g) may be associated with a higher incidence of side effects. A comprehensive literature review[146] revealed an incidence of acute respiratory failure of only 0.15% for patients treated with pharmaceutical-grade talc poudrage.

As an adjunct to surgical therapy, the most commonly employed material is talc. Sterile, asbestos-free talc is insufflated during thoracoscopy or thoracotomy to coat the visceral pleural surface. Typically, 3 to 5 g of talc are used.[145,147] A recent prospective cohort study of video-assisted thoracoscopic surgery (VATS) with talc poudrage evaluated the outcomes in more than 1400 patients with PSP undergoing surgery for recurrent pneumothorax (93%) or persistent air leak (7%).[148] The rate of recurrent pneumothorax was 0.2% in nonsmokers, 4.2% in active smokers, and 3.8% in those with a prolonged air leak.

Mechanical pleurodesis may be performed as part of a surgical procedure. It may consist of simple abrasion of the parietal pleural surface or may entail stripping of the parietal pleura (pleurectomy). The second method has a greater potential for complications, including injury to an intercostal neurovascular bundle or excessive bleeding from the large raw surface area. Also considered in this category is the use of an Nd:YAG laser or an argon beam coagulator, which essentially cauterizes the pleural surface.[149]

The performance of pleurodesis in someone who may need future thoracic surgery is somewhat debatable and relates to the degree of pleural symphysis that can be obtained and the method utilized. Currently, guidelines suggest evaluation for pleurodesis in patients with prolonged air leaks for greater than 4 to 5 days, in those with recurrent pneumothorax, and as part of the treatment of catamenial pneumothorax and pneumothorax associated with HIV.[3,116] Either chemical or mechanical pleurodesis may result in significant adhesion formation. Clearly there is a significant reduction in the incidence of recurrence. However, in some cases, there are concerns that future surgical procedures, such as pulmonary resection, open lung biopsy, and lung transplantation, may be hampered by this degree of pleural symphysis. The application of pleurodesis thus depends on an assessment of the risk of recurrent pneumothorax and the potential morbidity to the patient should a recurrence occur versus the potential for later operative procedures in the thorax. Although prior pleurodesis renders explantation of the native lung more difficult and increases the risk of intraoperative bleeding, it is not a contraindication to subsequent lung transplantation. One suggested compromise is limitation of the pleurodesis to the apical area, as this is the most common location for air leaks to occur. Later thoracic procedures may be done, albeit with more difficulty, by entrance inferior to the area of pleurodesis and subsequent adhesion lysis apically. Localized pleurodesis is not possible when it is performed as an adjunct to tube thoracostomy. A second potential compromise is the use of tetracycline analogues such as doxycycline or minocycline. Experimental studies and anecdotal reports indicate that with the use of tetracycline derivatives, the degree of pleural symphysis and density of adhesions are not as great as with talc or mechanical pleurodesis.[136,137,139,141,144]

■ Operative Therapy

Operative treatment (mechanical pleurodesis with or without stapling of blebs or pleurectomy) is generally thought to be the most effective in assuring expansion of the lung, with complete evacuation of the pleural space, and providing for the best means of reducing the risk of recurrence. In addition, it provides a means of potentially identifying an air leak and closing it. However, increased patient discomfort, risks of general anesthesia, and greater costs of the procedures, combined with moderate success of the less invasive methods, result in restricted application of surgery for pneumothorax.

Operative therapy is indicated in cases in which the abovementioned, less invasive techniques have failed, with persistence or recurrence of the pneumothorax, in cases of protracted air leak, or in some very selective cases of patients with limited pulmonary reserve. This risk of recurrence should include an assessment of the potential morbidity or mortality to the patient should another pneumothorax occur.

Longitudinal studies have indicated that the recurrence rate is approximately 30% after tube thoracostomy alone for treatment of a spontaneous pneumothorax. Among patients in whom the disease recurs once, the subsequent recurrence rate continues to increase.[150] Evidence suggests that a more definitive procedure—namely surgery—is indicated with the first recurrence. In patients with localized lung disease, such as congenital lobar emphysema or a single large bulla, surgery may be indicated for the initial episode of pneumothorax. Patients who have high-risk lifestyles, such as pilots or scuba divers, or patients who may not have ready access to medical care may possess a relative indication for surgical treatment of a first occurrence of spontaneous pneumothorax because of the risk to the patient should a pneumothorax occur. Patients who present with bilateral or tension pneumothorax may also fall in this category of morbidity assessment.

Patients with a pneumothorax from any cause who have a persistent air leak despite prolonged chest tube drainage should also be considered for operative therapy. An air leak that fails to close after 72 to 96 h of suction has a very low chance of closing spontaneously. This is the recommended time for surgical referral.[130] Finally, patients in whom the previous forms of therapy result in incomplete re-expansion of the lung should be considered for surgery. This situation may reflect loculation of the pneumothorax or trapping of the lung by a fibrotic "peel," which will require surgery to be released.

VATS has emerged as the preferred surgical approach when surgical intervention for pneumothorax is required. It is associated with less postoperative discomfort and decreased length of hospital stay compared with standard thoracotomy. The decreased morbidity is the result of the ability to examine the pleural space and manipulate the lung without significant muscle division or rib spreading.[147] In most cases, the technique requires general anesthesia with double-lumen endotracheal ventilation (single lung ventilation). Those patients who are at high risk (elderly or significant underlying lung disease) can undergo this procedure under local and epidural anesthesia.[151] Up to three separate ports are placed in the intercostal spaces to effect installation of the camera as well as manipulating devices. The entire lung can be inspected and a search for the air leak carried out. In general, the apical area is the most common location, and this area can then be closed with the use of a stapler. Stapled resection of bullae also can be performed. In patients with concomitant lung disease, particularly COPD, the staple line can be reinforced with the aid of bovine pericardium to minimize persistence of air leaks.[152] The pleural surface can then be abraded or talc insufflated, as mentioned above, to achieve some degree of pleural adhesion following re-expansion of the lung. Long-term follow-up of recurrence rates has shown results similar to those for open thoracotomy.

The less invasive nature of VATS compared to open thoracotomy has prompted earlier and more frequent surgical referral. While the risks associated with general anesthesia remain, overall costs are generally less than with thoracotomy owing to shorter hospital stay. The cost of VATS as an initial procedure for spontaneous pneumothoraces may be less in the course of the treatment of the disease compared with more conservative therapies for both PSP and SSP.[153] These conclusions, however, are not based on prospective randomized trials and should be verified in larger prospective studies.

Open Thoracotomy

Although VATS has supplanted thoracotomy as the surgical treatment of pneumothorax in many institutions, open thoracotomy remains a valuable option in the treatment of complicated cases.

Thoracotomy allows examination of the lung for the site of an air leak, enables lysis of previous adhesions that may lead to a loculated pneumothorax, and enables the release of a fibrotic peel that occasionally forms, leading to incomplete re-expansion of the lung. Recurrence rates are generally less than 2%.[154] Drawbacks include the potential risks associated with general anesthesia, increased costs, and the significant amount of patient discomfort. Discomfort is generally most severe with a standard lateral or posterolateral thoracotomy with muscle division and rib spreading.

In an effort to minimize the level of discomfort, variations have been developed, including the use of smaller incisions, the so-called muscle-sparing thoracotomies, and the axillary thoracotomy. Lung examination and air leak closure and possible pleurodesis or pleurectomy can then still be performed.[154]

SUGGESTED GUIDELINES FOR MANAGEMENT

Based on the relative efficacy of the various forms of therapy combined with relative risks for the major categories of pneumothorax, the following guidelines are suggested.

■ Primary Pneumothorax

Patients with a first-time uncomplicated PSP can be treated with observation or with interventional management. Observation should include a minimum of 4 to 6 h of observation and documentation that the patient's pneumothorax does not increase in size and the patient is able to walk comfortably, is physiologically stable, and does not require supplemental oxygen. Initial interventional management can include simple aspiration or placement of a small 8 to 10 French catheter. Subsequent small-tube thoracostomy is indicated for failure of simple aspiration or observation (enlarging pneumothorax, persistent tachypnea >30 breaths per minute, saturation $<90\%$ on room air). Patients not requiring hospitalization should be discharged with analgesia and close follow-up with repeat chest radiograph.[155]

Patients who undergo successful tube thoracostomy with complete lung re-expansion and absence of an air leak may opt for a chemical pleurodesis while the chest tube is in place. Since the risk of recurrence is low (approximately one in five), most physicians recommend patients in good general health defer this procedure until a second pneumothorax occurs. Patients with persistent air leaks for more than 72 to 96 h after insertion of a chest tube should be referred for surgical therapy. Because of the progressive increase in risk of recurrence, patients with their first recurrence of a primary pneumothorax should undergo chemical pleurodesis or be referred for surgical therapy, preferably VATS, with stapling of any air leak and pleural abrasion or chemical pleurodesis.

■ Secondary Pneumothorax

In general, therapy for secondary pneumothorax should be more aggressive because of the higher rate of recurrence due to the underlying lung pathology. Specific conditions with pneumothorax as a common occurrence are as listed below.

COPD

Most cases of pneumothorax in patients with COPD should be treated with tube thoracostomy. In patients who are not good surgical candidates, chemical pleurodesis with a tetracycline derivative (minocycline or doxycycline) or talc should be performed once there is complete re-expansion and absence of an air leak. In COPD patients who are good surgical candidates or in patients with a persistent air leak longer than 72 to 96 h, more aggressive therapy should be considered.[47] Recommended therapy includes VATS or thoracotomy with talc insufflation, mechanical pleurodesis, stapling resection, and/or pleurectomy. This approach provides a more effective way of achieving a lower risk of recurrent pneumothorax.

Cystic Fibrosis (CF)

Although there are no clinical trials to guide therapy in patients with CF and pneumothorax, retrospective reports offer suggestions for management. Clinically stable patients with small pneumothoraces may be followed with observation. Clinical instability or large pneumothorax requires chest tube placement. Pleurodesis should be considered after recurrence of a large pneumothorax. Surgical pleurodesis is associated with fewer recurrences in the CF population and is the preferred modality. Noninvasive positive-pressure ventilation, positive expiratory pressure devices, and intrapulmonary percussive ventilation should be stopped until the pneumothorax has resolved, but aerosols need not be held. Because of the future possibility of lung transplantation for patients with CF, localized pleurodesis is recommended as an adjunct to surgical closure of the air leak.[49,50]

AIDS

For most patients with AIDS who present with a pneumothorax, tube thoracostomy is the primary mode of initial treatment. Because of the high primary and secondary treatment failure rates, patients who have no air leak with complete lung re-expansion should undergo talc slurry pleurodesis. For patients with a persistent air leak who are deemed to be poor surgical risks because of severe debilitation, a Heimlich valve may be utilized. For patients who are deemed good risks for surgery, VATS with talc insufflation is recommended.[56]

Other Conditions

While there are insufficient data to make firm recommendations for all situations, some suggestions are offered. Patients with pneumothorax secondary to iatrogenic causes may be treated with observation or aspiration according to the guidelines previously listed. In patients who have a small traumatic pneumothorax (<35 mm on CT scan), simple observation can be considered. Tube thoracostomy should be considered in patients with larger pneumothorax, those with hemopneumothorax, and patients with limited physiologic reserve. Patients who experience a pneumothorax while on positive-pressure ventilation should usually have tube thoracostomy placement to avoid progression to a tension pneumothorax.[156] Patients who present with bilateral pneumothoraces or a tension pneumothorax, but who are not on positive-pressure ventilation, should have placement of tube thoracostomy. Further therapy with regard to chemical pleurodesis versus surgery is dependent on underlying lung pathology.

Persistent Air Leak

A persistent air leak is usually caused by a broncho- or alveolopleural fistula.[157] In more recent literature, it is generally accepted to be present if an air leak lasts more than 5 days,[157,158] although definitions vary among different authors. Initial conservative management is advised by most guidelines. Some persistent air leaks take as long as 14 days to resolve without surgical interventions.[3] A retrospective study showed that 97% of patients with primary spontaneous pneumothorax resolved at around this time frame.[159] Patients with underlying disease may take longer. The use of Heimlich valves has been recommended by guidelines as a conservative measure as an option in this setting prior to more invasive options (Fig. 79-13). Persistent air leaks can result in increased morbidity, prolonged hospitalization, and increased health care costs to the patient and often require surgical intervention in patients with SSP and adequate pulmonary reserve.[160] In general, guidelines recommend observation for at least 4 days before surgical evaluation to close the air leak.[116] Surgical interventions can be performed by thoracotomy or thoracoscopically. As mentioned above, these interventions include chemical or mechanical pleurodesis; oversewing or stapling the air leak; creating muscle, omental or pericardial flaps; or occasionally lobectomy.[161] The success rate of surgical closure for bronchopleural fistulas has been reported to be between 80% and 95% but carries additional operative risk.[158] Because of limited pulmonary reserve, many patients may not be operative candidates.

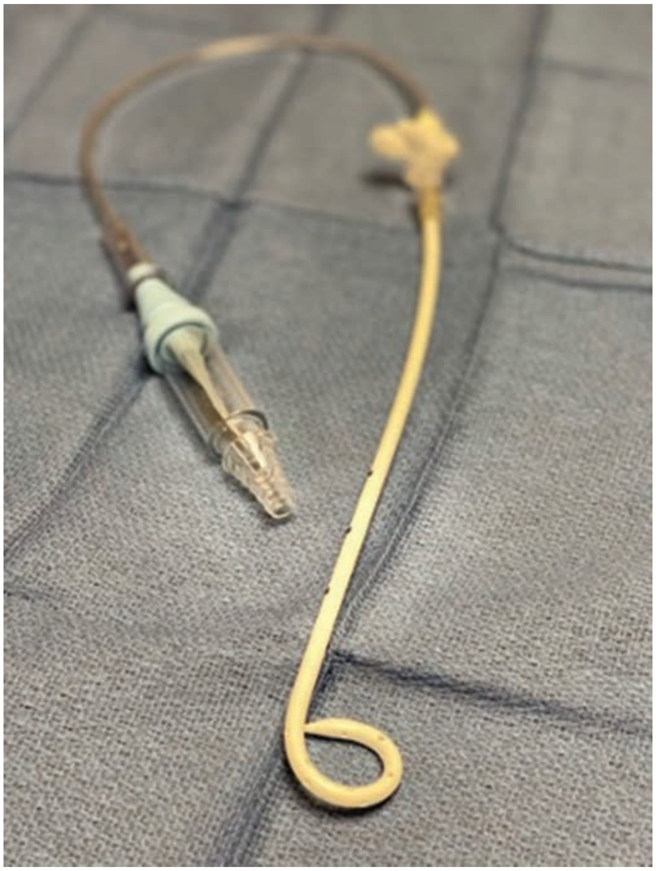

Figure 79-13 A Heimlich valve attached to a pig-tail chest tube catheter.

In patients who are not surgical candidates, several less invasive procedures can be tried. Perhaps the least invasive procedure is the use of an autologous blood patch. Usually, 50 to 100 mL of venous blood is instilled through the chest tube and flushed with 10 mL of normal saline. Elevating the chest tube about 2 feet above the chest allows the blood to remain in the pleural space. The chest tube should not be clamped since the presence of a persistent air leak could result in a tension pneumothorax. According to a review of the literature, a blood patch pleurodesis was effective in approximately 90% of patients;[162] however, in our experience, the success rate is significantly lower.

Chemical agents have also been instilled into the pleural space to seal a persistent air leak. The technique used is similar to that used for an autologous blood patch. Tetracycline derivatives have been shown to be safe in an animal model of pleural air leaks and did not induce an inflammatory reaction in the lung. A retrospective study of PSP patients and persistent air leak showed a success rate of 63%; however, long-term follow-up to determine recurrence was not reported.[163] The safety of using talc in patients with persistent air leaks has not been defined. A retrospective study in patients with air leaks after surgical lung resection used talc in most of their patient population and reported a success rate of greater than 95%.[160] Since talc has been associated with acute lung injury, we believe further studies demonstrating safety are required before it can be recommended.

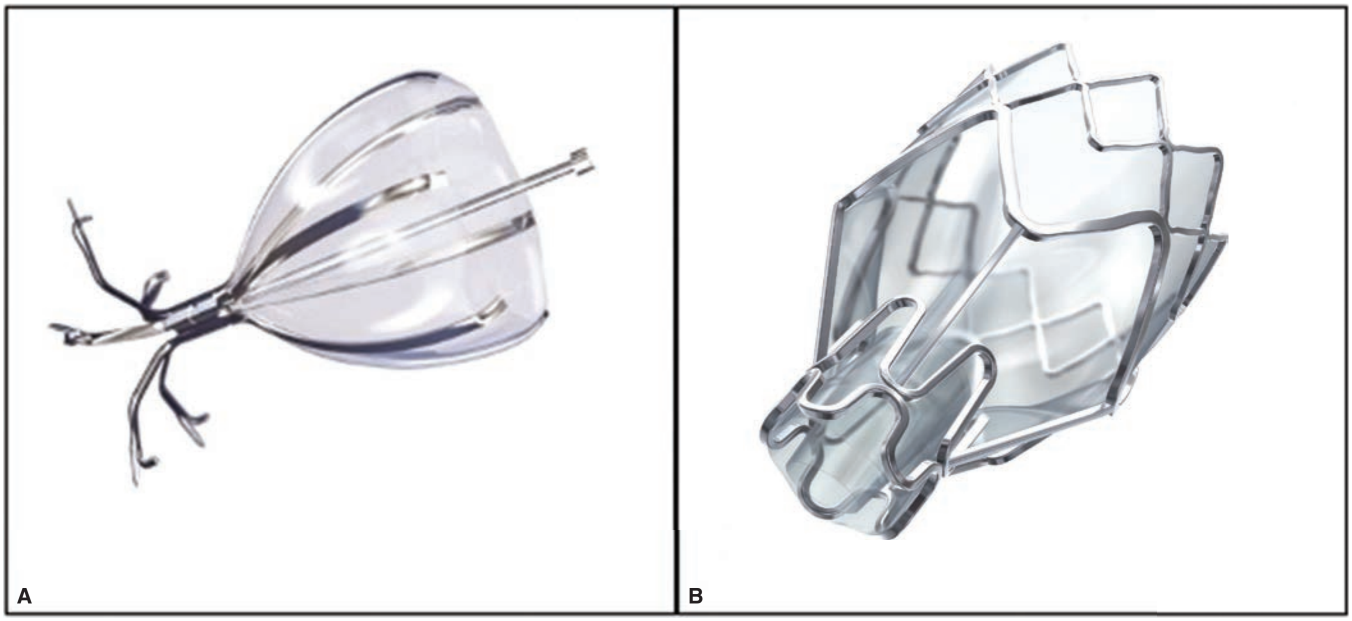

Figure 79-14 Available bronchial valve systems in the United States. **A.** Spiration Valve System (SVS). **B.** Zephyr Valve PulmonX Corporation. (***A.*** *Image courtesy of Olympus America Inc, Center Valley, PA.* ***B.*** *Reproduced with permission from PulmonX Corporation, Redwood City, CA.)*

Current guidelines do not recommend considering bronchoscopic approaches as first-line treatment in the management of persistent air leaks. However, since the publication of these guidelines, endobronchial techniques such as endobronchial one-way valves have been developed and utilized for persistent air leaks, especially in postsurgical patients (Fig. 79-14). A retrospective multicenter study[164] showed successful valve implantation in 91% of patients with complete resolution of air leak in 88%, reduction of air leak in 9%, and no benefit in 3%. A systematic review[161] with more than 200 SSP patients undergoing placement of endobronchial valve placement for persistent air leaks revealed complete resolution rates ranging from 47.5% to 100% with an observed recurrence of 9%. Unfortunately, there are no randomized clinical trials exploring the benefit of one-way endobronchial valves, and the current cost of endobronchial valves is significant.

Air Travel

The U.S. Federal Aviation Administration (FAA) guidelines require commercial airlines to be pressurized to an equivalent of 2438 m (8000 ft) at the maximum operating altitude ("cabin altitude").[165] Due to pressure–volume relationships from Boyle's law, it is estimated that the volume of residual pneumothorax can expand by as much at 38% at this altitude compared with sea level.[166] This has been postulated to occur in the air trapped in blebs or bullae as well, predisposing these patients to pneumothorax in flight.[167] Most recent guidelines recommend that patients should obtain a chest x-ray to confirm resolution of pneumothorax before flight, and wait an additional 7 days (or 14 days, in the case of traumatic pneumothorax) before flying.[166] However, these recommendations are based largely on expert opinion and available case reports. Patients found to have bullae or blebs, and those with cystic lung diseases including lymphangioleiomyomatosis and Birt-Hogg-Dubé syndrome, are considered higher risk for in-flight pneumothorax.[167] Overall, it is important for clinicians to discuss the risk of air travel in patients who are at risk for spontaneous pneumothorax and to explain the potential options to prevent recurrence in all patients with either primary or secondary spontaneous pneumothoraces.

CHAPTER 80

Nonneoplastic Disorders of the Mediastinum

Luis F. Tapias
Cameron D. Wright

INTRODUCTION

The mediastinum may be the site of a variety of neoplastic (Chapter 82) and nonneoplastic disorders. In this chapter, we first describe the anatomy of the mediastinum, including its boundaries, compartments, and distribution of lymphatics. We then consider the important clinical entities of pneumomediastinum, acute mediastinitis, and chronic mediastinitis before concluding with a discussion of spontaneous mediastinal hemorrhage.

ANATOMY OF THE MEDIASTINUM

The boundaries defining the mediastinum, as well as its subdivisions or compartments, and important anatomic considerations regarding mediastinal lymphatics are discussed below.

Boundaries

The mediastinum is defined as the potential space between the two pleural cavities bounded by the sternum anteriorly, the vertebral column posteriorly, the thoracic inlet superiorly, and the diaphragm inferiorly (Fig. 80-1).[1] The major mediastinal structures are the heart and great vessels, the trachea and main bronchi, and the esophagus, all closely related to one another and connected by loose connective tissue. Also present are the thymus, lymph nodes, nerves, and fat. Hence, air or infection can disseminate widely throughout the mediastinal space, contained laterally only by the mediastinal pleural reflections. The mediastinum communicates with both the neck and the retroperitoneum, and these portals can also serve as routes of egress from the mediastinum. Fascial planes connect the neck, mediastinum, and retroperitoneum and thus facilitate movement of air or infection from one location to another.

Compartments

Several subdivisions of the mediastinum have been emphasized in the surgical and radiologic literature, but there is no consensus. Most often, three compartments are proposed: anterior, middle (visceral), and posterior (paravertebral sulcus) (Fig. 80-2).[2] The boundaries of these divisions are not agreed upon, further emphasizing their nonanatomic origins. Shields proposed a simple three-compartment subdivision in 1972 that makes both anatomic and surgical sense. Each of these compartments extends from the thoracic inlet superiorly to the diaphragm inferiorly. The anterior compartment is bounded by the sternum and the anterior surface of the pericardium and great vessels. The middle (visceral) compartment extends from the posterior limit of the anterior compartment to the anterior surface of the vertebral columns. The posterior compartment (paravertebral sulcus) extends from the anterior surface of the vertebral column to the anterior surface of the paravertebral ribs. The structures in these compartments are listed in (Table 80-1). The pericardial sac is the only true compartment of the mediastinum, and it provides a strong barrier to infection. Subdividing the mediastinum into compartments proves most helpful when one is interpreting a plain radiograph that shows a

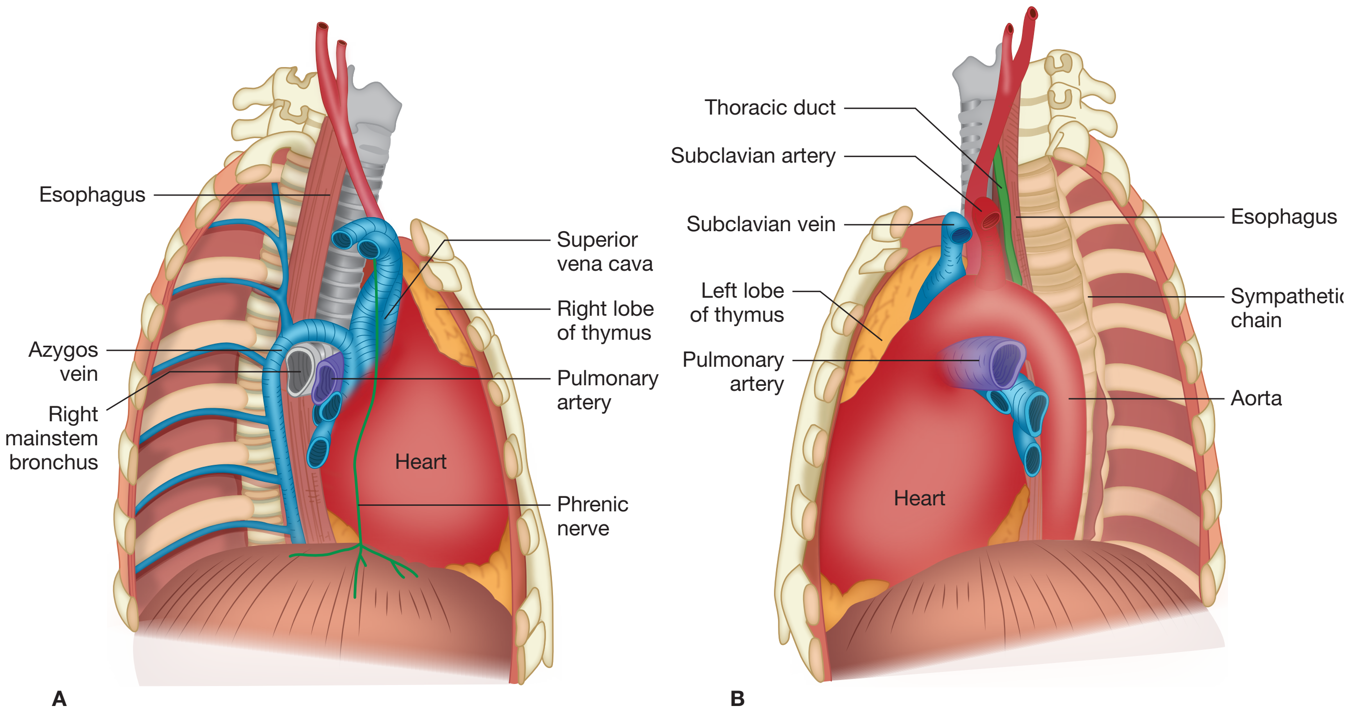

Figure 80-1 **A.** Lateral view of the mediastinum as seen through a right thoracotomy. **B.** Lateral view of the mediastinum as seen through a left thoracotomy. *(Reproduced with permission from Shields TW: Mediastinal Surgery. Philadelphia, PA. Lea & Febiger; 1991.)*

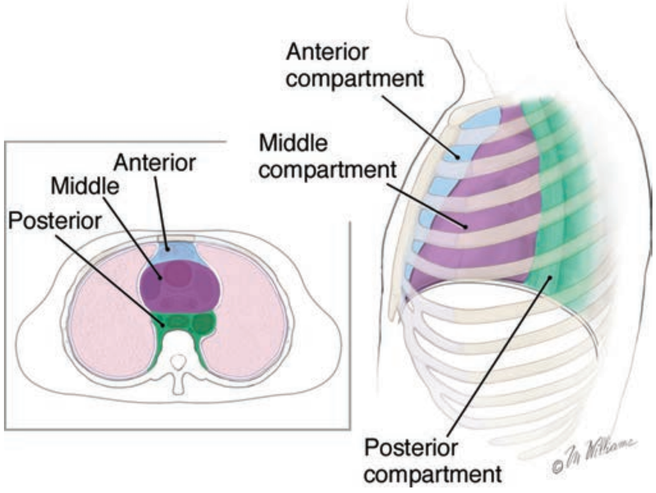

Figure 80-2 The mediastinum is divided into three compartments: anterior, middle, and posterior. This is particularly useful when dealing with mediastinal tumors for the convenience of diagnosis and surgical approach. *(Reproduced with permission from Marcia Williams.)*

mediastinal mass. Knowledge of the contents of the involved compartment facilitates arriving at a proper diagnosis. However, due to the lack of true anatomic boundaries, it should be emphasized that diseases or masses of the mediastinum often extend from one compartment to another.

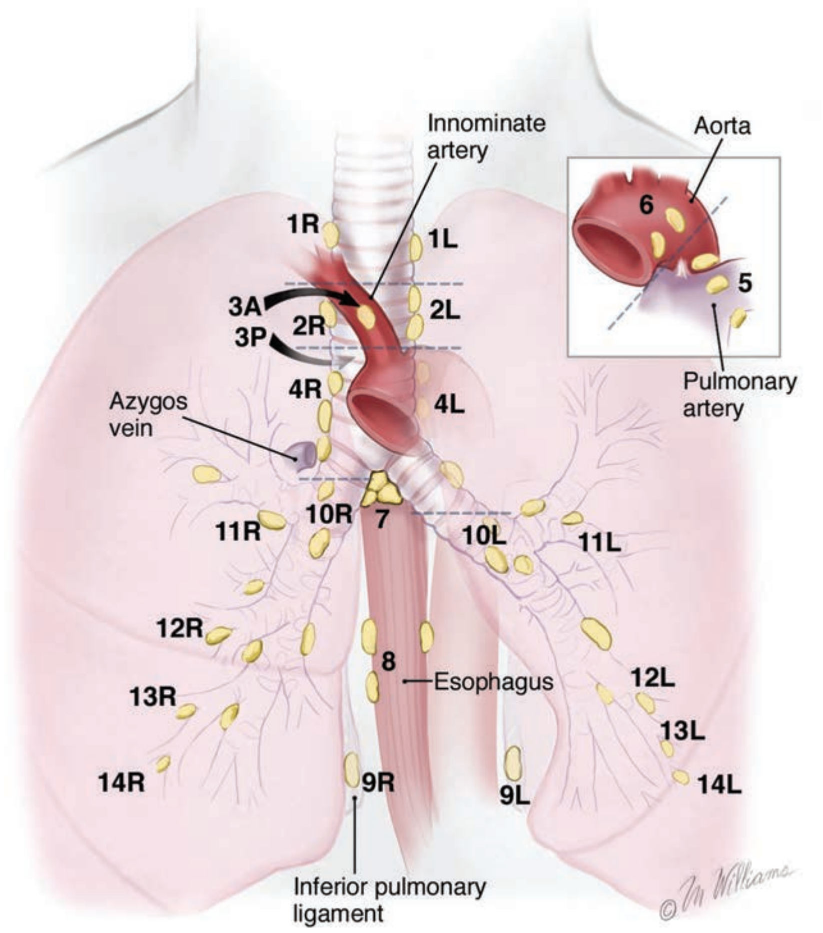

Figure 80-3 Lung cancer lymph node stations map. Note that any double-digit numeral is considered N_1 disease. A, anterior; L, left; P, posterior; R, right. *(Reproduced with permission from Marcia Williams.)*

TABLE 80-1 Contents of Mediastinal Compartments

Anterior	Middle	Posterior
Thymus gland	Pericardium	Azygos and hemiazygos veins
Pericardial fat	Heart	
Lymph nodes	Trachea and main bronchus	Thoracic duct
	Esophagus	Sympathetic trunk
	Aorta	
	Phrenic and vagus nerves	Intercostal nerves
	Lymph nodes	

■ Lymphatics

The mediastinal lymphatic system is quite complex and variable. Mediastinal lymph nodes are interconnected; thus, involvement of one group of lymph nodes in a pathologic process frequently leads to involvement of other groups. Similar to subdividing the mediastinum into compartments, naming individual nodal stations is somewhat arbitrary and leads to the mistaken notion that these nodal stations are discrete. To the contrary, the mediastinum is covered in a dense network of lymphatic vessels and lymph nodes with no predictable boundaries. Nonetheless, there are commonly accepted nodal stations that have clinical importance, especially in the staging of thoracic malignancies, particularly lung cancer. The lymph node map proposed by Naruke in 1978 has been widely accepted and serves as a standard for communication of lymph node involvement (Fig. 80-3).[3] Briefly, lymph node stations denominated by a single digit (i.e., stations 1 through 9) correspond to true mediastinal lymph nodes, whereas stations denominated by two digits (i.e., stations 10 and above) correspond to lymph nodes that are within the pleural sac and thus are extramediastinal.

PNEUMOMEDIASTINUM

Pneumomediastinum (mediastinal emphysema) is an uncommon condition characterized by the accumulation of air or gas in the mediastinum. Depending on the cause, management may be expectant or may involve specific treatment directed at the underlying abnormality.

■ Anatomic Considerations

Pneumomediastinum is frequently associated with other forms of extra-alveolar air, including pulmonary interstitial emphysema, pneumopericardium, pneumothorax, subcutaneous emphysema, pneumoretroperitoneum, and pneumoperitoneum. The key to understanding the distribution of extra-alveolar air lies in the recognition of the common fascial planes that unite these areas. In the neck, the deep layer of the deep cervical fascia ensheathes the trachea and esophagus as they descend into the mediastinum. The trachea and esophagus are thus enclosed in this visceral space; therefore, air can readily travel from the mediastinum to the neck or retroperitoneum (Fig. 80-4).[4] This fascial plane extends into the hilum of the

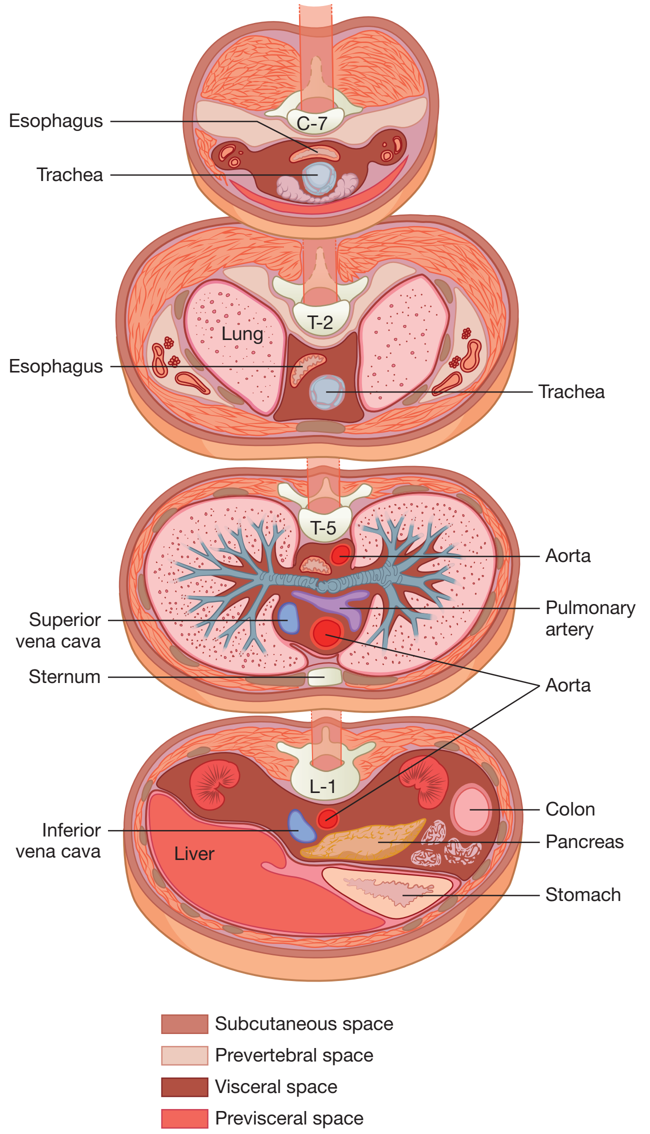

Figure 80-4 Soft tissue compartments of the neck, thorax, and abdomen demonstrating continuity of visceral space between regions.

lung and merges with the bronchovascular sheaths that surround the terminal bronchioles, arteries, and veins. The bronchovascular sheath also merges with and is continuous with the pericardium. After alveolar rupture, air enters the perivascular interstitium and dissects proximally within the bronchovascular sheath toward the mediastinum (Fig. 80-5). Air can then enter the pericardial space, resulting in pneumopericardium, or it may dissect along the adventitia of the great vessels (Fig. 80-6). More commonly, mediastinal air can decompress by extension into the cervical, subcutaneous, and retroperitoneal spaces. A pneumomediastinum that ruptures into the free pleural space results in a pneumothorax. Pneumothorax may also result from air dissecting out toward the visceral pleural surface of the lung and rupturing. Macklin, in 1944, in an elegant experimental cat model, confirmed this theory of progression of extra-alveolar air following alveolar rupture.[5] Pneumomediastinum usually results from a ruptured alveolus due to a Valsalva maneuver or mechanical ventilation. There are many other possible sources, however, that must be considered when the physician has to manage a patient with pneumomediastinum (Table 80-2). Dental procedures, especially those on the mandible with the addition of compressed air to maintain a clear field, are an occasional cause of mediastinal emphysema.

TABLE 80-2 Etiology of Pneumomediastinum

- Upper respiratory tract
  - Head and neck infection
  - Fracture of facial bones
  - Trauma to hypopharynx and larynx (especially intubation)
  - Dental procedures (especially mandibular)
- Lower respiratory tract
  - Trauma
  - Bronchoscopy, especially therapeutic bronchoscopy (i.e., YAG laser, rigid core-out, dilation, and transbronchial biopsy)
- Lung
  - Trauma
  - Surgery
  - Spontaneous alveolar rupture
    - Straining and Valsalva maneuver
    - Local airway obstruction
    - Scuba diving
    - Mechanical ventilation
- Gastrointestinal tract
  - Esophageal perforation
  - Perforated viscus
- Infection
  - Acute mediastinitis
  - Descending necrotizing mediastinitis
- Air from outside the body
  - Trauma
  - Surgery (especially mediastinoscopy, tracheostomy, and sternotomy)
  - Pneumoperitoneum (especially with laparoscopic hiatus hernia repair)

Spontaneous Pneumomediastinum

Idiopathic spontaneous pneumomediastinum is a rare self-limited condition that most commonly affects young adult men. Hamman is credited with the original description of this entity in 1939, including the characteristic crepitation synchronous with the heartbeat heard in these patients (Hamman sign).[6] The majority of patients with spontaneous pneumomediastinum have predisposing factors that cause increase in airway pressure, which leads to alveolar rupture.[7–9] Most commonly, this results from straining against a closed glottis (i.e., the Valsalva maneuver) as during vomiting, coughing, or exercising. Other mechanisms include sudden and/or severe increases in lung volume, as occur during marijuana smoking, vaping, inhaling of cocaine, or during anxiety attacks or seizures. Activities that involve environmental pressure changes, like diving, have been reported in association with pneumomediastinum. Localized airway obstruction from tumor, foreign bodies, asthma, or parenchymal lung disease also can cause alveolar rupture. An accurate history is most important to define the mechanism in a particular patient.

Macia and colleagues[8] reported an incidence of spontaneous pneumomediastinum of 22 cases per 1,000,000 emergency

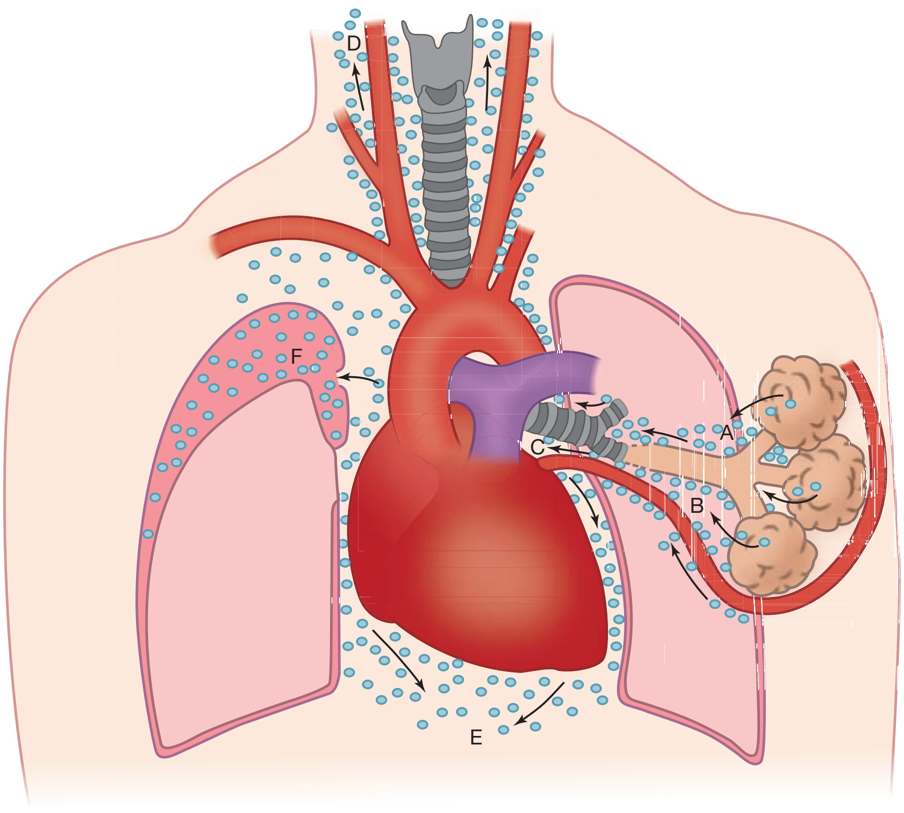

Figure 80-5 Possible routes of air following alveolar disruption. Air from the alveolus (**A**) enters the perivascular interstitium (**B**), dissecting proximally within bronchovascular sheaths toward the mediastinum (**C**). As mediastinal pressure rises, decompression occurs in cervical (**D**), subcutaneous, and retroperitoneal (**E**) soft tissue spaces. A pneumothorax is possible if the pleura (**F**) is ruptured.

department visits. Spontaneous pneumomediastinum almost always presents with substernal pain, often pleuritic, which may radiate to the neck or back. Additional symptoms that may occur, either separately or in combination, include dyspnea, dysphagia, odynophagia, and dysphonia. Air in the subcutaneous tissues of the neck produces a characteristic change in voice quality, a higher-pitched nasal tone that the experienced clinician easily recognizes. Examination often reveals palpable subcutaneous emphysema in the neck. Auscultation of the chest may reveal a crunching or clicking sound heard over the pericardium, synchronous with the heartbeat (Hamman sign). Low-grade fever is present in about one-third of cases and mild leukocytosis in about one-half. Nonspecific electrocardiographic changes, such as ST-T wave changes and ST elevation, also may be present. A chest radiograph usually demonstrates a thin radiolucent strip along a mediastinal fascial plane, most commonly along the left heart border. The aortic knob may be highlighted as well (Fig. 80-6). Computed tomography (CT) is more sensitive in detecting air than are plain radiographs (Fig. 80-7) and can provide information on alternative diagnoses. Air may be evident deep in the neck as well as in the subcutaneous tissue.

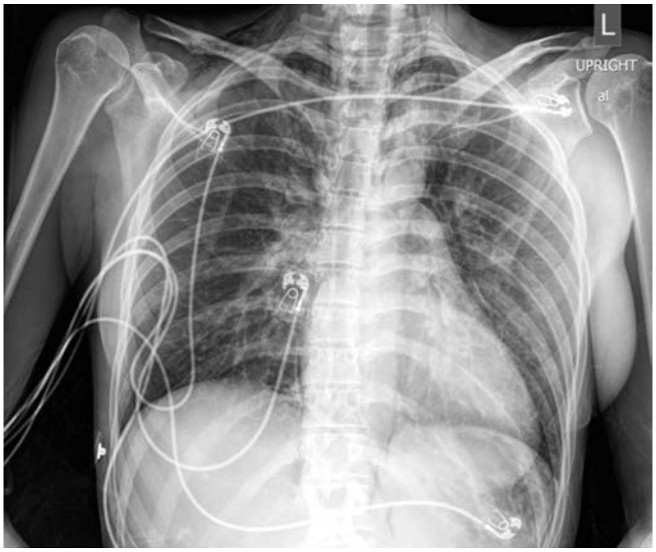

Figure 80-6 Chest radiograph of a patient with spontaneous mediastinal emphysema. Mediastinal air is seen along the right heart border and the upper mediastinum tracking into the neck.

The differential diagnosis is broad and includes musculoskeletal, pleural, pulmonary, tracheobronchial, cardiac, and esophageal causes. Although most patients who present are not acutely ill, an occasional patient may suffer an acute, catastrophic onset with hypotension and hemodynamic compromise. Esophageal perforation is the condition most likely to be confused with spontaneous pneumomediastinum. Worrisome features suggestive of esophageal perforation include recent esophageal instrumentation, a history of esophageal problems, severe retching, the presence of a pleural effusion or mediastinal fluid on CT imaging, or shock. Bakhos et al.[10] showed that patients with pneumomediastinum secondary to esophageal perforation are older (58 vs. 19 years), have a higher white blood cell count (15×10^3 vs. 12×10^3), and more frequently present with pleural effusions on imaging (54% vs. 0%) when compared with patients with spontaneous pneumomediastinum. In a review of 249 patients with pneumomediastinum on chest radiography or CT, Potz et al.[11] found that 24 patients (10%) had an esophageal perforation. Factors associated with the presence of esophageal perforation were older age (63 vs. 25 years), history of hemoptysis, presence of a pleural effusion, and leukocytosis (18.1×10^3 vs. 10.9×10^3). A contrast esophagogram should be obtained immediately if there is any question of an esophageal perforation, since a delay in making this diagnosis often proves fatal. A high index of suspicion regarding esophageal perforation should always be present whenever a patient presents with mediastinal emphysema.

Treatment of spontaneous pneumomediastinum is supportive and is primarily directed at pain relief and reassurance. Appropriate management of contributing causes such as foreign bodies, asthma, and parenchymal lung disorders should be instituted. The patient should be followed both clinically and radiographically to exclude another cause for mediastinal emphysema and to detect a possible pneumothorax. Prompt resolution is the rule. Supplemental oxygen to hasten reabsorption (similar to that proposed for pneumothorax) has been reported but is probably not necessary. Needle aspiration

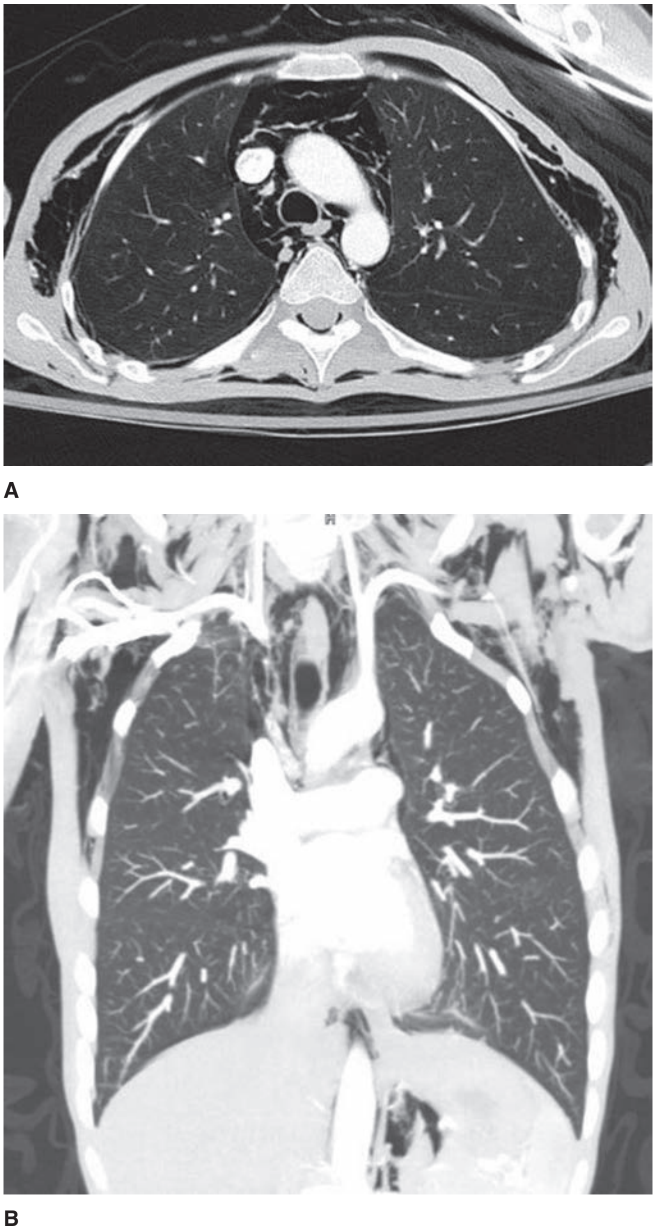

Figure 80-7 **A.** Axial CT scan image illustrating classic mediastinal emphysema from spontaneous pneumomediastinum. **B.** Coronal CT image again illustrating mediastinal emphysema.

or skin incision to relieve subcutaneous emphysema is almost never necessary and is discouraged. Prophylactic tube thoracostomy is unnecessary. However, a concomitant pneumothorax can occur and may require intervention to evacuate air and re-expand the lung. For patients who present with minimal findings and a clear inciting factor (such as coughing), only a short period of observation in the emergency department is required. Some patients require admission for a short period of pain control and observation, with an excellent prognosis. Recurrence is rare.

A recent large case series reinforces these principles. Iyer et al.[9] reported on 62 adult patients with spontaneous pneumomediastinum over an 11-year period at a large academic medical center. The median age was 30, and 66% were men. Pre-existing lung disorders were identified in 44% of patients, including interstitial lung disease (18%), asthma (15%), bronchiolitis obliterans syndrome (8%), bronchiectasis (8%), chronic obstructive pulmonary disease (8%), primary or metastatic lung malignancy (6%), and cystic lung lesions (3%). Precipitating factors were clearly identified in only one-third of cases and included inhalational drug use (10%), upper respiratory infection with coughing (8%), asthma exacerbation (6%), severe retching (6%), and athletic activities (3%). Common symptoms included chest pain (63%), cough (45%), dyspnea (44%), neck pain (18%), light-headedness (18%), dysphagia (5%), and dysphonia (5%). Common signs included subcutaneous emphysema (45%). Hamman sign was not observed in this series, although it was reported in 12% of cases in another published series.[8] Simple chest radiographs demonstrated pneumomediastinum in 90% of patients imaged. In the other 10%, the diagnosis was reached by CT of the chest; in half of these patients, the volume of pneumomediastinum was too small to be detected with chest radiography. A concomitant pneumothorax was identified in one-third of patients; however, only a minority required placement of a chest tube. Additional diagnostic procedures were performed in 44% of patients to exclude aerodigestive injuries as the cause of the pneumomediastinum. Investigations included contrast esophagography (35%), bronchoscopy (6%), and esophagogastroduodenoscopy (3%). In all cases, findings were normal. Median length of stay was 2.5 days, and all patients were treated with supportive care. After a median follow-up of 6 months, only 1 patient (2%) experienced recurrence of pneumomediastinum, which was attributed to persistent inhalational drug use.

■ Pneumomediastinum Associated with Mechanical Ventilation

Mechanical ventilation is commonly associated with pneumomediastinum and may lead to life-threatening tension pneumothorax. Alveolar rupture results from high peak inspiratory pressures, which increase alveolar pressures in patients with abnormal airways or parenchyma (decreased compliance). Classic predisposing factors include high tidal volumes, high levels of positive end-expiratory pressure (PEEP), and patient–ventilator dyssynchrony. Air trapping with occult positive end-expiratory pressure (auto-PEEP) is an underrecognized cause of barotrauma. It is not clear if a particular mode of ventilation (pressure-controlled vs. volume-limited) is associated with a decreased incidence of barotrauma. Pneumomediastinum associated with mechanical ventilation has been observed recently in approximately 10% of patients in the setting of the coronavirus disease 2019 (COVID-19) pandemic caused by infection with SARS-CoV-2,[12] which has resulted in an unprecedented number of patients requiring invasive mechanical ventilation. Similar rates of pneumomediastinum associated with mechanical ventilation were observed during the SARS-CoV-1 outbreak in 2003 (12%).[13]

Unlike spontaneous mediastinal emphysema, pneumomediastinum occurring in a patient on mechanical ventilation is potentially catastrophic because of its frequent association with tension pneumothorax. The chest radiograph should be closely examined to detect even a small pneumothorax, and if such is present, tube thoracostomy should be promptly performed. Obviously, a sudden deterioration marked by hypotension and increased pulmonary pressures should prompt immediate attention with insertion of unilateral or bilateral chest tubes, depending on the clinical examination. The issue of inserting a tube prophylactically is controversial if pneumomediastinum without pneumothorax is identified. At a minimum, a thoracostomy tray should be kept at the patient's bedside. Removing the patient from mechanical ventilation as soon as possible is an ideal way of mitigating risk of barotrauma. Since this is seldom possible, efforts should be directed at minimizing alveolar distention. These efforts include relief of bronchospasm, optimizing sedation to minimize "fighting" the ventilator, reducing tidal volume and PEEP, and manipulation of inspiratory flow and timing to reduce auto-PEEP.

Pneumopericardium

Pneumopericardium as a form of barotrauma is much more frequent in neonates, presumably due to immature fascial planes. Hemodynamically significant tamponade is also much more likely to occur in infants than adults and has resulted in collapse and death. Pericardial drainage with a subxiphoid tube should be performed promptly in the neonate. In the adult, drainage should be performed only if there is hemodynamic embarrassment.

ACUTE MEDIASTINITIS

Acute mediastinitis is a life-threatening disorder that causes severe morbidity in the afflicted patient. All three mediastinal compartments can be affected: the anterior compartment most commonly after sternotomy for cardiac surgery, the middle compartment usually from esophageal perforation, and the posterior compartment from direct extension from the neck, lung, or spine. Iatrogenic perforation of the esophagus secondary to instrumentation is the most common cause of acute mediastinitis in the United States.

Mediastinitis from Esophageal Perforation

Instrumental perforation of the esophagus now accounts for more than one-half of all esophageal perforations.[14] Perforation is more common after rigid esophagoscopy, dilation of a stricture, and pneumatic dilation for achalasia, but it also occurs after variceal sclerosis, esophageal tube placement (nasogastric, Sengstaken–Blakemore, and stents), and simple flexible esophagoscopy. Boerhaave syndrome (post-emetic rupture) was first described in 1724 but still represents a diagnostic challenge and remains a major consideration in patients with otherwise unexplained mediastinitis (Fig. 80-8). Instrumental perforation of the esophagus most frequently is localized to the cervical esophagus, whereas Boerhaave syndrome usually results in perforation of the distal thoracic and abdominal esophagus.

Patients with mediastinitis due to esophageal perforation usually present with the abrupt onset of severe substernal chest pain. In cases of Boerhaave syndrome, onset of pain is preceded by forceful vomiting or retching. Dyspnea is common even in the absence of pneumothorax. Shock may ensue quickly, and the patient usually appears gravely ill. Examination reveals tachypnea, tachycardia, fever, hypotension, splinting of the chest and abdomen, and cervical emphysema. Radiographic findings include cervical or mediastinal emphysema, pneumothorax, and pleural effusion. A contrast esophagogram (usually with water-soluble contrast) should be performed immediately when the diagnosis is suspected, but one should be aware that this study has a false-negative rate of 10%. A chest CT scan is the next best study in a patient in whom esophageal perforation is suspected but who has a negative esophagogram. Prompt diagnosis and, therefore, a high index of suspicion are essential, as the frequency of complications and the mortality rate are directly dependent on the time elapsed between perforation and treatment.[15] The differential diagnosis is broad and includes perforated ulcer, acute pancreatitis, myocardial infarction, pneumonia, aortic dissection, and pulmonary embolism.

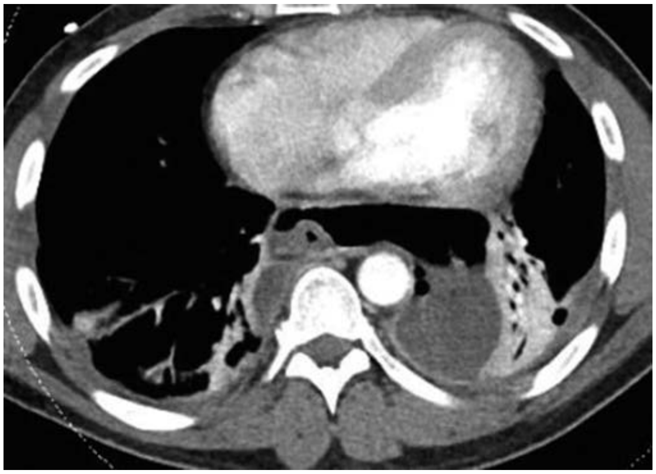

Figure 80-8 CT image of a patient with a delayed diagnosis of a post-emetic esophageal rupture. There is extensive air surrounding the lower esophagus with bilateral loculated effusions and left lower lobe atelectasis.

Treatment should be instituted urgently and involves surgical debridement of necrotic tissue, secure closure of the perforation, correction of any distal obstruction, and wide drainage, usually performed through a left thoracotomy.[16] Recently, management of esophageal perforations with covered esophageal stents and image-directed percutaneous drainage has gained traction and is a widely accepted treatment strategy.[17,18] However, esophageal stents have a higher failure rate in cases of perforations of the cervical esophagus or gastroesophageal junction and in perforations greater than 6 cm in length.[19] Appropriate broad-spectrum antibiotics with anaerobic coverage and the maintenance of proper nutrition are also integral components of the management plan. Esophagectomy is occasionally required in the presence of a perforated, non-dilatable stricture, a destroyed esophagus in which direct repair is not possible, or cancer. Nonoperative treatment is occasionally appropriate and may be instituted in highly selected cases (i.e., contained, asymptomatic instrumental perforations) in which a significant interval has passed and the patient is clinically stable. Mortality is less than 10% if the perforation is recognized and repaired within 24 h, whereas mortality, the rate of reintervention, and hospital stay increase if more than 24 h have elapsed between perforation and repair. Mortality rises even higher with advanced patient age.

Tracheobronchial Perforation

Tracheobronchial perforation is rare and is most commonly seen following trauma or instrumentation. Less common causes include anastomotic dehiscence after lung transplantation or airway surgery and necrotizing infections involving the airway. Intubation is now the most frequent cause of tracheobronchial injury, but injury can be avoidable with gentle and proper technique. The incidence of tracheobronchial injuries is estimated at 1 in every 75,000 single-lumen intubations and 1 in every 575 percutaneous dilatation tracheostomies.[20]

Blood in the airway, airway obstruction (infrequent), subcutaneous and mediastinal emphysema, and pneumothorax are the common presenting signs. Severe mediastinitis is rare after tracheobronchial disruption, presumably due to the less noxious nature of its contents and better containment. Diagnosis is suspected on clinical grounds and is confirmed with CT and/or bronchoscopy. Prompt recognition and surgical consultation for operative repair are necessary and yield excellent results, although small tears in the cervical trachea or those involving the membranous wall of the trachea only may often be managed conservatively with antibiotics alone, without operation.[21]

Descending Necrotizing Mediastinitis

Mediastinitis occasionally develops after severe deep head and neck infections that originate from the mouth, oropharynx, or hypopharynx.[22–28] Extension of the cervical infection down the layers of the deep cervical fascia into the mediastinum leads to this syndrome of descending necrotizing mediastinitis. Downward spread is aided by gravity, negative intrapleural pressure, and lytic dissolution of fascia and fat. The deep cervical fascia consists of three layers: the superficial (buccopharyngeal) layer, the middle (visceral) layer, and the deep layer that is further subdivided into the alar and prevertebral layers. All layers originate from the base of the skull. The superficial layer terminates at the superior chest. The visceral layer terminates as a continuation of the pericardium. The potential space between the superficial and middle layers, called the retropharyngeal space, allows infection to descend to the middle of the chest. The alar layer terminates at the diaphragm. The potential space between the middle and the alar layer confines infection above the diaphragm. Rare infections between the alar and prevertebral layers may allow the spread of infection below the diaphragm. Endo et al.[25] classified descending necrotizing mediastinitis according to the extent of the infection to guide the surgical management according to this classification: type 1, infection above the carina, type IIA, infection to the level of the lower anterior mediastinum, and type IIB, infection involving the lower anterior and posterior mediastinum.

The criteria for diagnosing descending necrotizing mediastinitis include (1) severe head and/or neck infection, (2) radiographic evidence of mediastinitis, (3) evidence of necrotizing infection, and (4) establishment of a relationship between the cervical infection and necrotizing mediastinitis.[24] Previously, these infections had a fulminant, often lethal course with mortality as high as 40%. Ridder et al.[23] reported a large series and performed a meta-analysis of collected series that illustrate the cardinal features of this important clinical problem. Patients present with odynophagia (66%), neck swelling (41%), neck pain (21%), dyspnea (21%), and chest pain (5%). Signs include fever (100%) and swelling and redness of the oropharynx (69%). About two-thirds of patients have comorbidities that are associated with immunosuppression or chronic illnesses, such as diabetes, malnutrition, advanced age, renal failure, alcoholism, liver cirrhosis, or underlying malignancy. Common causes include tooth abscesses, pharyngitis, peritonsillar abscess, epiglottis, and perforation of the pharynx. Pharyngeal or tonsillar origin of infections seems to be more frequent than odontogenic. Most patients present with a mixed aerobic and anaerobic infection, reflective of the oropharyngeal microflora. A period of delay of either presentation or diagnosis is common.

CT with intravenous contrast should be performed on all severe neck infections and suspected cases of descending necrotizing mediastinitis to identify radiologic signs of mediastinitis that may not be clinically apparent (Fig. 80-9). *Streptococcus* species are the most common aerobic organisms, and *Bacteroides* and *Peptostreptococcus* species are the most common anaerobic organisms isolated. The mainstay of treatment consists of antibiotic therapy, drainage of abscesses, and debridement of devitalized tissue. Broad-spectrum antibiotics should be started promptly upon clinical suspicion of this diagnosis. All patients require cervical incision, exploration, drainage, and treatment of the underlying condition. Many patients also require transthoracic drainage most commonly by thoracotomy or video-assisted thoracoscopy (VATS). Often, image-guided percutaneous drainage is appropriate to help drain mediastinal abscesses. In a review of 89 cases of descending necrotizing mediastinitis in Japan, Sumi[29] reported transcervical drainage in 28%, VATS in 24%, thoracotomy in 24%, and percutaneous drainage in 17%. Frequently, patients had a combination of approaches to achieve complete drainage of the infection. Many patients require several trips to the operating room for serial debridement and drainage procedures. The mean length of stay is 36 days reflecting the severity of this illness. Recent series report an average mortality of 10% to 15%.

Finally, airway management needs to be considered, as these infections are associated with severe oropharyngeal and supraglottic edema that can lead to prolonged intubation or extremely difficult reintubation should the endotracheal tube become dislodged. Therefore, tracheostomy is often required, as this facilitates airway control.

■ Mediastinitis from Direct Extension

Mediastinitis has been reported after endoscopic procedures used for diagnostic purposes in conditions of the mediastinum or lung cancer staging, including endoscopic ultrasound (EUS) and endobronchial ultrasound (EBUS) with needle aspiration.[30,31] A review of 7345 cases of EBUS with transbronchial needle aspiration (TBNA)[32] documented an incidence of mediastinitis of 0.1% (7 cases). Seeding of the mediastinum is attributed to the translocation of oropharyngeal or lower respiratory flora by the needle puncture, particularly, when targeting necrotic or cystic lesions or lymph nodes. It has been demonstrated that up to 7% of patients experience bacteremia after EBUS-TBNA, with cultures demonstrating typical oropharyngeal microorganisms.[33] Moreover, culture of needle washings is positive in up to one-third of cases. However, infectious complications after EBUS-TBNA are so infrequent that routine preprocedural antibiotic prophylaxis has not been recommended.[34]

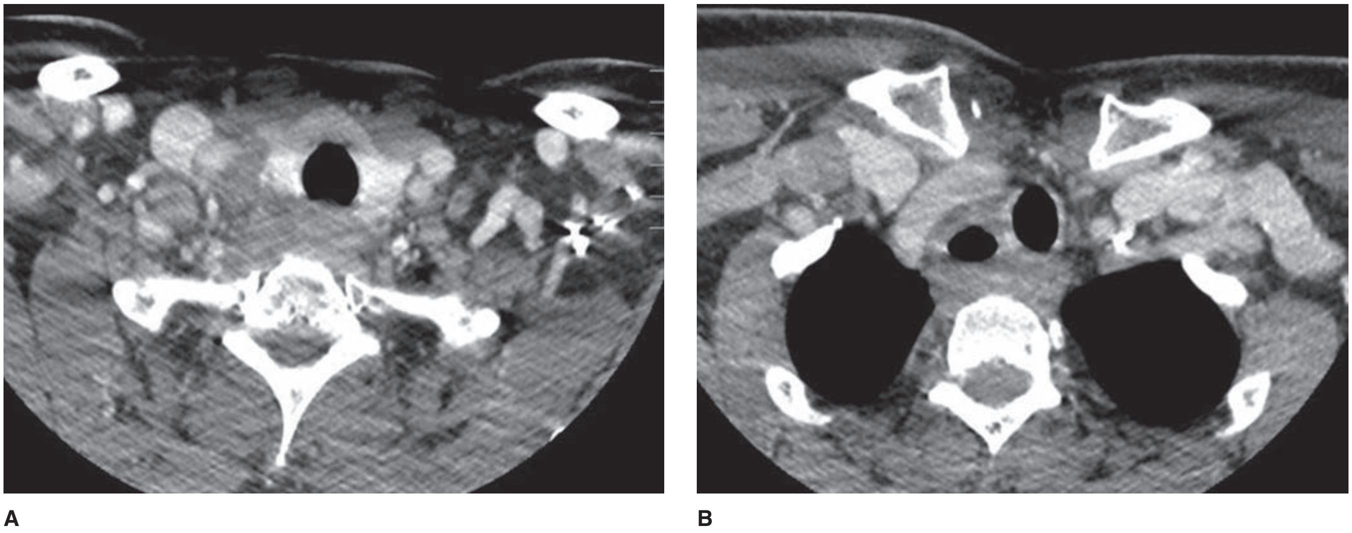

Figure 80-9 Representative CT images from a patient with descending necrotizing mediastinitis from a peritonsillar abscess. **A.** CT image at the base of the neck with soft tissue swelling along the right carotid sheath and also tracking down the retropharyngeal space to the mediastinum. **B.** CT image from the upper chest in this patient with a right superior mediastinal abscess from descending necrotizing mediastinitis.

Necrotizing pneumonias may cause mediastinitis by direct extension, most often in immunocompromised patients. Aspergillosis of the posterior mediastinum has been reported with increasing frequency and is highly lethal. Treatment involves reversal of immunosuppression (if possible), appropriate antibiotic therapy, and surgical drainage and debridement.

Pancreatitis can extend from the retroperitoneum into the mediastinum and may present as a mediastinal process with evidence of mediastinitis. Pancreatic pseudocysts can also erode into the mediastinum and cause pleural effusions with increased levels of amylase. Treatment is directed at providing adequate drainage of the pseudocyst, usually by internal drainage into the stomach. Pleural effusions may require tube thoracostomy drainage.

■ Poststernotomy Mediastinitis

Sternal wound infection with resulting mediastinitis is a condition most relevant after cardiac surgery. The incidence remains low at 0.5% to 1% of all sternotomies, but such infection is a source of major morbidity, prolonged hospital length of stay, and significant mortality (0%–30%; average, 15%). Risk factors include prolonged preoperative stay, advanced age, smoking, BMI >30 kg/m^2, chronic obstructive pulmonary disease, diabetes, renal failure, reoperation, use of internal thoracic artery grafts, blood transfusions, poor technique during sternotomy or closure of the sternotomy, and re-exploration for bleeding.[35,36] *Staphylococcus aureus* is the most common causative organism. Other organisms commonly isolated include *Staphylococcus epidermidis*, various gram-negative organisms, *Candida* species, and atypical mycobacteria. The etiology appears to be a combination of intraoperative contamination and hematogenous seeding of mediastinal clot in the early postoperative period.

Most patients with poststernotomy mediastinitis have an insidious presentation with low-grade fever and leukocytosis, wound problems (erythema, drainage, sternal instability), and eventually bacteremia. Infections caused by gram-negative organisms tend to manifest earlier than those caused by gram-positive organisms. Most infections occur within the first or second week following the operative procedure. A high index of suspicion must be maintained so that an early diagnosis can be made and appropriate treatment instituted. The diagnosis is established clinically based on symptoms and physical exam findings (e.g., unstable sternum, erythema or discharge from the surgical site). CT imaging can aid in making the diagnosis and establishing the extent of the infection. Exploration in the operating room remains the definitive diagnostic and therapeutic maneuver, and material should be obtained for culture at that time if it has not been obtained before or has been unrevealing.

If the infection is relatively early and the bony sternum appears viable, debridement, drainage, and saline (or antibiotic) irrigation with reclosure are indicated.[36] Although it may seemingly violate time-honored surgical principles (leaving contaminated wounds open, to close by secondary intention), primary closure of the early, infected sternum yields excellent results in many patients if adequate debridement is carried out. Of course, proper and prolonged antibiotic therapy is necessary. Reported mortality rates approach zero for these early infections if managed appropriately. Late sternal wound infections with mediastinitis present a more formidable challenge, due in part to the extensive sternal osteomyelitis and necrotic soft tissue that, when debrided, result in significant dead space, thereby creating a favorable environment for continued bacterial proliferation and persistent infection. The presence of prosthetic material, such as sutures, Teflon pledgets, or prosthetic grafts further complicates the problem and may lead to catastrophic hemorrhage with a fatal outcome. Mediastinitis in the presence of a prosthetic aortic graft is a particularly disastrous complication. Most surgeons favor extensive sternal debridement, usually with total sternal excision and rotation of pectoralis muscle flaps (bilateral) or transposition of gastrocolic omentum to fill the dead space with viable tissue. More recently successful outcomes have been reported with the use of negative-pressure wound therapy (vacuum-assisted closure [VAC]).[37,38] Caution is required to protect the right ventricle or coronary bypass grafts when using negative-pressure wound therapy to prevent erosion with subsequent hemorrhage.[39]

■ Anthrax Mediastinitis

Anthrax is caused by *Bacillus anthracis*, which has a nearly worldwide distribution existing in the soil in the form of spores. It causes infection in farm animals and rarely in humans in contact with infected animals or contaminated animal products. Clinically, four different presentations of anthrax exist: cutaneous, gastrointestinal, injectional, and inhalational. Anthrax, particularly its most lethal inhalational form, was prominent in the mainstream media after the bioterrorism attacks of 2001 in the United States when anthrax spores were sent through the mail. The potential use of anthrax as a biologic weapon was suspected after an outbreak in the Soviet Union in 1979 (in the current area of Yekaterinburg, Russia), when at least 66 people died to inhalational anthrax following the suspected accidental release of anthrax spores to the atmosphere from a research facility. Autopsy studies from this outbreak have established the key pathologic processes of inhalational anthrax.[40] The inhalation of anthrax spores allows entry into the lungs with subsequent transport to the mediastinal lymph nodes by alveolar macrophages. Hemorrhagic necrosis of the mediastinal lymph nodes with hemorrhagic mediastinitis quickly ensues followed by widespread dissemination, including meningitis. Death is common. Gram-positive bacilli are usually present in tissue specimens. A total of 22 cases of anthrax were documented after the 2001 attacks in the United States with 5 deaths.[41,42] Diagnosis is confirmed by culture, polymerase chain reaction assays, or histopathology.

Treatment of inhalational anthrax involves combination antimicrobial therapy including a fluoroquinolone, such as ciprofloxacin; a protein inhibitor, such as linezolid; and a drug with excellent penetration of the central nervous system, such as meropenem.[42] Adjunctive therapies include antitoxins (monoclonal antibodies, anthrax immune globulin), and drainage of pleural and pericardial effusions and ascites, as these are rich in toxins.

CHRONIC MEDIASTINITIS

Several important clinical entities within the spectrum of chronic mediastinitis, including mediastinal granuloma, fibrosing mediastinitis, and compression syndromes arising from fibrosing mediastinitis, are presented below.

■ Mediastinal Granuloma

Granulomatous mediastinitis is a disease of the mediastinal lymph nodes usually resulting from infection by *Histoplasma capsulatum* and occasionally from tuberculosis, other fungi, and sarcoidosis. In certain areas of the country (e.g., Ohio and Mississippi river valleys) where *Histoplasma* is endemic, this disease is fairly common. Coalescence of caseous necrosis in mediastinal lymph nodes with dystrophic calcification can result in a single large mass that incites a considerable fibrotic response, which can result in encapsulation and produce a mediastinal granuloma.[43] The right paratracheal area is the most common site for development of an encapsulated mass. When calcification is absent and the patient presents with what appears to be mediastinal adenopathy, a tissue diagnosis is required to exclude malignancy. With progressive increase in the size of this “benign” mass, compression of the tracheobronchial tree, superior vena cava, pulmonary vessels, or esophagus can occur. In a report from the Mayo Clinic, 35% of patients with mediastinal granuloma

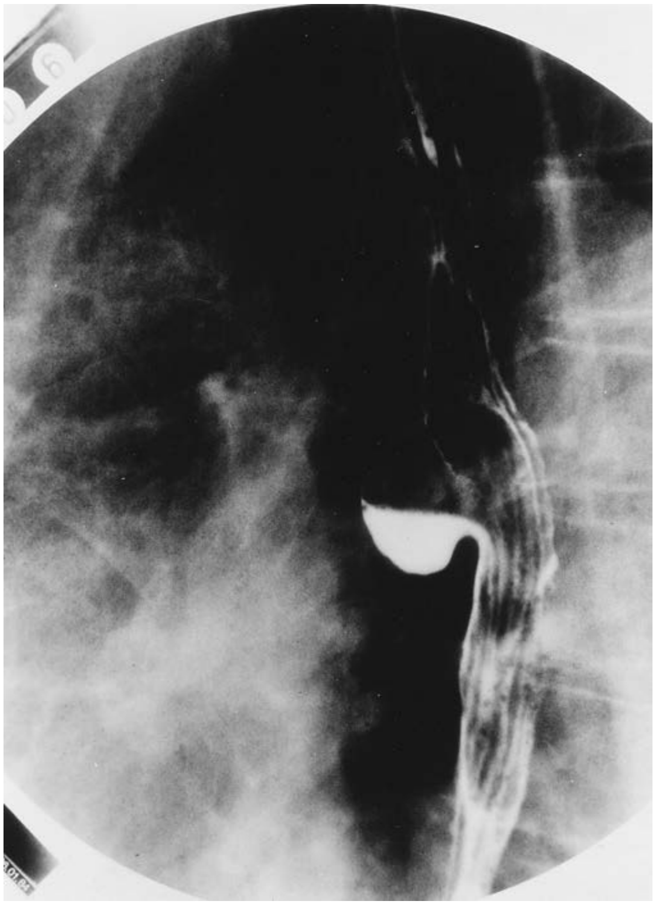

Figure 80-10 Barium swallow of an elderly woman with a history of treated tuberculosis with symptomatic midesophageal traction diverticulum adjacent to calcified subcarinal lymph nodes.

went on to develop mediastinal fibrosis over a 2-year period.[43] Based on such reports, most authors suggest that there exists a spectrum of diseases ranging from mediastinal granuloma to fibrosing mediastinitis, with varying degrees and extension of inflammation and desmoplastic reaction. Caseating lymph nodes can also erode into and rupture in the esophagus, be associated with traction esophageal diverticula (Fig. 80-10), and erode into the airway, causing obstruction or bleeding.

Mediastinal granulomas should be excised if symptomatic. Although complete excision is sometimes possible, the intense surrounding fibrosis places important structures at risk for operative injury. Evacuation of the granulomatous mass is usually a safer option. Specimens for culture and special stains should be obtained at the time of operation, but organisms can rarely be identified or grown in culture.

Mediastinal lymph nodes involved by the granulomatous process may become calcified as individual masses and—because of the proximity of lymph nodes to the tracheobronchial tree—ultimately erode into the airway. The presence of calcified lymph node masses within the bronchi is referred to as *broncholithiasis*. Erosion into the airway, if it occurs, does so over a prolonged period of time and may remain clinically silent, only to be noted if a bronchoscopy is performed for some other indication. Broncholithiasis may also present with symptoms of cough, obstruction, or bleeding. Symptomatic broncholithiasis should prompt bronchoscopy for documentation of findings. Rarely, if ever, should broncholiths be removed bronchoscopically, the exception being the occasional "stone" that is completely free within the bronchus. An effort to remove a broncholith that is not completely detached from the wall of the bronchus may be accompanied by catastrophic hemorrhage due to their close proximity and adherence to pulmonary artery branches. Most symptomatic broncholiths should be removed at thoracotomy, where the pulmonary artery may be managed. These can be extremely difficult and hazardous operations and should be carried out by thoracic surgeons experienced in the management of granulomatous disease. Usually lobectomy or segmentectomy is required, since removal of the calcified mass will almost certainly take a portion of the bronchial wall.

Fistulas occurring between the trachea and esophagus or esophagus and mediastinum as a result of granulomatous lymphadenitis should be closed and reinforced with viable tissue.[44] There is no consensus regarding management of large asymptomatic mediastinal granulomas, but some have recommended excision to forestall the development of compression syndromes or fibrosing mediastinitis.

Fibrosing Mediastinitis

Fibrosing mediastinitis results from extensive chronic inflammation with deposition of fibrous connective tissue, mainly in the visceral compartment of the mediastinum. It represents the end of the spectrum of diseases that, most commonly, are presumed to start with a mediastinal granuloma. Fibrosing mediastinitis may cause a variety of clinical syndromes due to the compression or obstruction of vital mediastinal structures by the dense fibrous tissue reaction that is present (see below).[45] In North America fibrosing mediastinitis is most commonly associated with *Histoplasma capsulatum* infection. Other rare causes include tuberculosis or other mycobacterial infections, infection with other fungi (e.g., aspergillosis, blastomycosis, cryptococcosis, mucormycosis), sarcoidosis, silicosis, exposure to the drug methysergide (an ergot derivative used in the treatment of refractory migraines), autoimmune disorders (e.g., Behçet disease, granulomatosis with polyangiitis, IgG4 disease), rheumatic fever, radiation therapy, trauma, and familial multifocal fibrosclerosis.[46–52] Fibrosing mediastinitis is labeled as idiopathic if there is no identifiable cause, which can occur in 10% to 20% of cases.

Goodwin et al.[53] proposed the most widely accepted hypothesis that fibrosing mediastinitis results from an excessive immune reaction to fungal, mycobacterial, or other antigens in a susceptible individual that results in ongoing inflammation and fibrogenesis. Strock et al.[54] found that the human leukocyte antigen HLA-DQB1*04:02 is associated with histoplasmosis-related fibrosing mediastinitis, further supporting the notion that an abnormal immune response is responsible for this phenomenon. In addition, Richmond et al.[55] explored potential genetic susceptibility to developing fibrosing mediastinitis by studying genome-wide single nucleotide polymorphisms (SNPs) in 58 patients and comparing them with 7115 controls. They found 16 SNPs in 14 genes that were differentially expressed in patients with fibrosing mediastinitis (3 SNPs involving the gene HYDIN located in chromosome 1), thus raising the possibility that the exaggerated fibrotic response seen in these patients has genetic underpinnings.

Pathologic features include the presence of dense fibrotic tissue surrounding the trachea and hila of the lungs, often extending into contiguous structures. Compression of the airway, esophagus, superior vena cava, pulmonary arteries, or pulmonary veins may occur because of this process. Histologic features include dense hyalinized collagenous tissue, aggregates of plasma cells and lymphocytes, and occasionally granulomas. Cultures are usually negative, as are special stains for organisms; however, efforts should be made to try to identify an inciting pathogen. Some cases present with radiographic features that suggest malignancy, particularly if calcification is minimal, leading to surgical biopsies for diagnosis.

McNeeley et al. recently reported a review of imaging of fibrosing mediastinitis.[56] The chest radiograph is usually abnormal in fibrosing mediastinitis, but findings are usually nonspecific. The most common findings include mediastinal widening, lymphadenopathy, and calcified nodes. Contrast-enhanced CT is the imaging modality of choice and shows fibrotic tissue with variable enhancement. Multiplanar reformatted views are especially helpful in demonstrating compression of vessels and airways and for planning an intervention. A practical differential diagnosis for granulomatous fibrosing mediastinitis includes lung cancer, mediastinal nodal metastases (especially sclerosing adenocarcinomas), sclerosing non-Hodgkin lymphoma, nodular sclerosing Hodgkin lymphoma, and tuberculosis. In a recent review, Garrana et al.[57] differentiated the imaging findings in focal (i.e., granulomatous) and diffuse fibrosing mediastinitis (i.e., idiopathic, autoimmune, drug or radiation induced). CT imaging of patients with focal disease reveals localized infiltrative mediastinal soft tissue, predominantly in the right paratracheal or subcarinal regions. Calcifications are common. Extrathoracic calcified granulomas might suggest a previous histoplasmosis infection. On the other hand, cases of diffuse fibrosing mediastinitis show a diffuse infiltrative soft tissue lesion often involving multiple mediastinal compartments. Calcifications are rare. Extrathoracic findings can include retroperitoneal fibrosis, sclerosing cholangitis, or features suggestive of autoimmune pancreatitis. In both instances, positron emission tomography (PET) measuring the uptake of ^{18}F-fluorodeoxyglucose (FDG) is variable and not reliable for diagnosis. However, some authors have reported cases with a well-documented increase in FDG uptake on PET in areas of mediastinal or retroperitoneal fibrosis, which can be used to monitor disease activity and response to anti-inflammatory treatments with good correlation.[58,59]

Fibrosing mediastinitis may be asymptomatic in up to 40% of patients, discovered incidentally on imaging studies obtained for other reasons. In the remaining patients, symptoms are primarily caused by compression of vital mediastinal structures, including major vessels, airway, and esophagus, as detailed in the following sections.

The most common mediastinal compression syndrome seen in fibrosing mediastinitis is the superior vena cava syndrome, which occurs in 20% to 50% of patients.[45] Although malignant disease account for the vast majority of cases of superior vena cava syndrome, fibrosing mediastinitis is the most common benign cause. Patients present with distention of the veins in the neck; edema and plethora of the face, neck, and arms; and central nervous system complaints such as headache and visual disturbances. Men often note as a first sign an increase in collar size, and symptoms become worse upon bending over. Because this syndrome is usually of gradual onset, venous collaterals develop over the anterior chest wall and, in many patients, provide adequate decompression (Fig. 80-11). Confirmation of the diagnosis of superior vena cava syndrome is easily made with contrast CT or venography, which demonstrate blockage of contrast at the thoracic inlet and the presence of collateral vessels. Bilateral upper extremity venograms demonstrate the precise anatomy of the involved veins and are helpful if surgical decompression is contemplated. Surgical bypass is reserved for patients with intractable symptoms and is performed

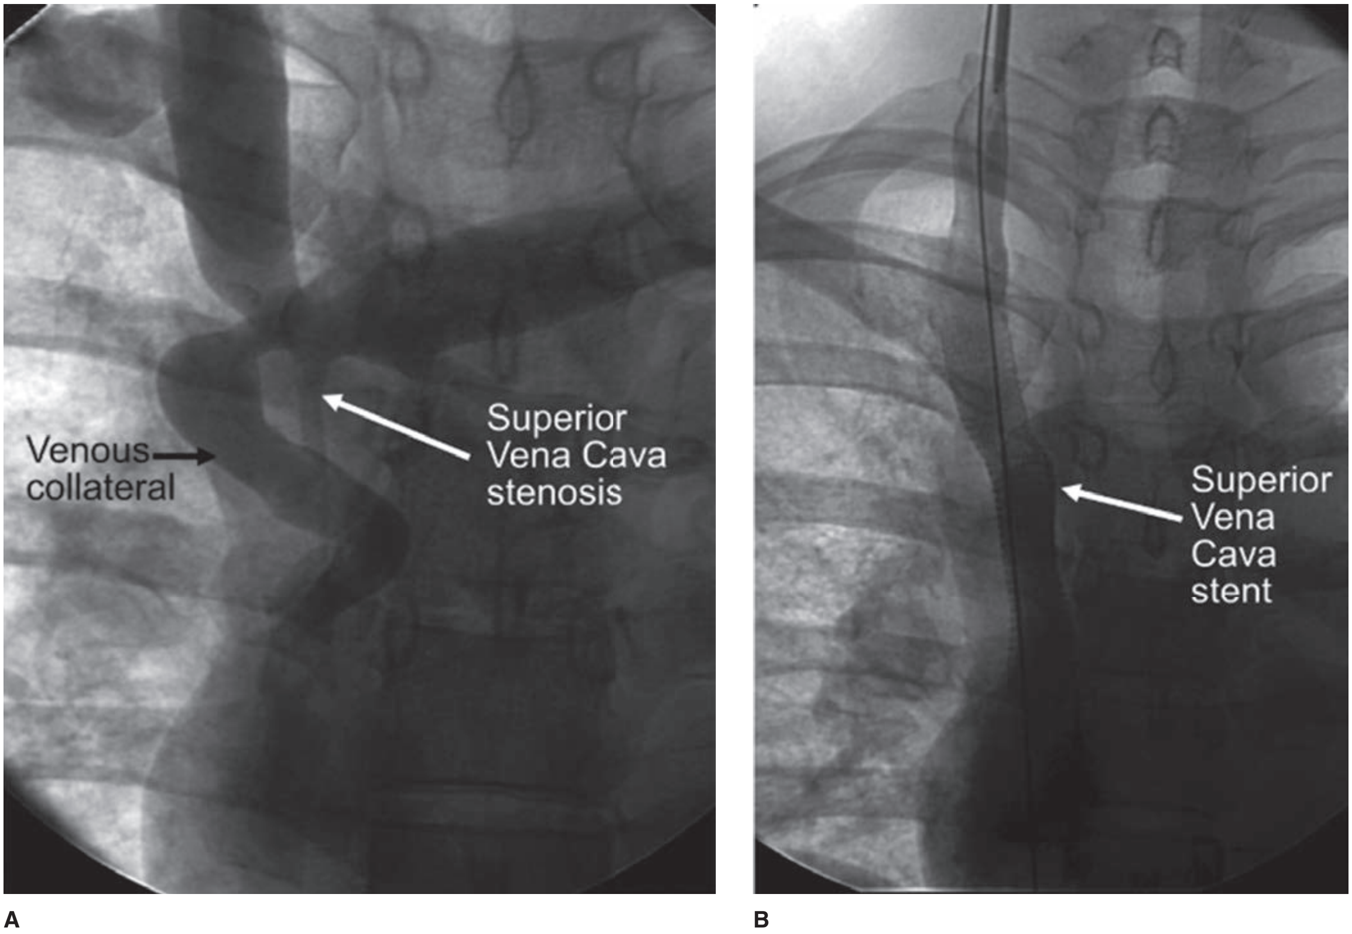

Figure 80-11 **A.** Venography demonstrates stenosis of the superior vena cava (SVC, *white arrow*) with a well-developed venous collateral *(black arrow)* due to fibrosing mediastinitis. **B.** Following stenting, there is significant improvement in the size of the SVC *(white arrow)*. *(Reproduced with permission from Fender EA, Widmer RJ, Knavel Koepsel EM, et al. Catheter based treatments for fibrosing mediastinitis. Catheter Cardiovasc Interv. 2019;94(6):878–885.)*

by connecting an unobstructed large brachiocephalic vein to the right atrial appendage with a graft of either a saphenous vein or an externally supported polytetrafluoroethylene graft. Favorable long-term results have been reported. Percutaneous angioplasty and stenting of a stenotic superior vena cava has been reported.[60] In one of the largest series of endovascular interventions in fibrosing mediastinitis,[61] 12 patients underwent endovascular stenting for superior vena cava syndrome. This resulted in increased SVC luminal caliber, decreased pressure gradients, and symptomatic improvement in all patients. However, 7 (58%) of these patients experienced restenosis and required repeated interventions. Median time to recurrence was 24 months.

Tracheobronchial compression also is common and leads to dyspnea, obstructive pneumonias, wheezing, hemoptysis, cough, atelectasis, and the middle lobe syndrome (Fig. 80-12). A localized stenotic area sometimes can be dilated, but often pulmonary resection is required. Resection is the procedure of choice if chronic infection has been present. Bronchoscopic interventions are appropriate if lung parenchyma remains normal. The bronchoscopic placement of stents into the trachea and/or mainstem bronchi may allow for

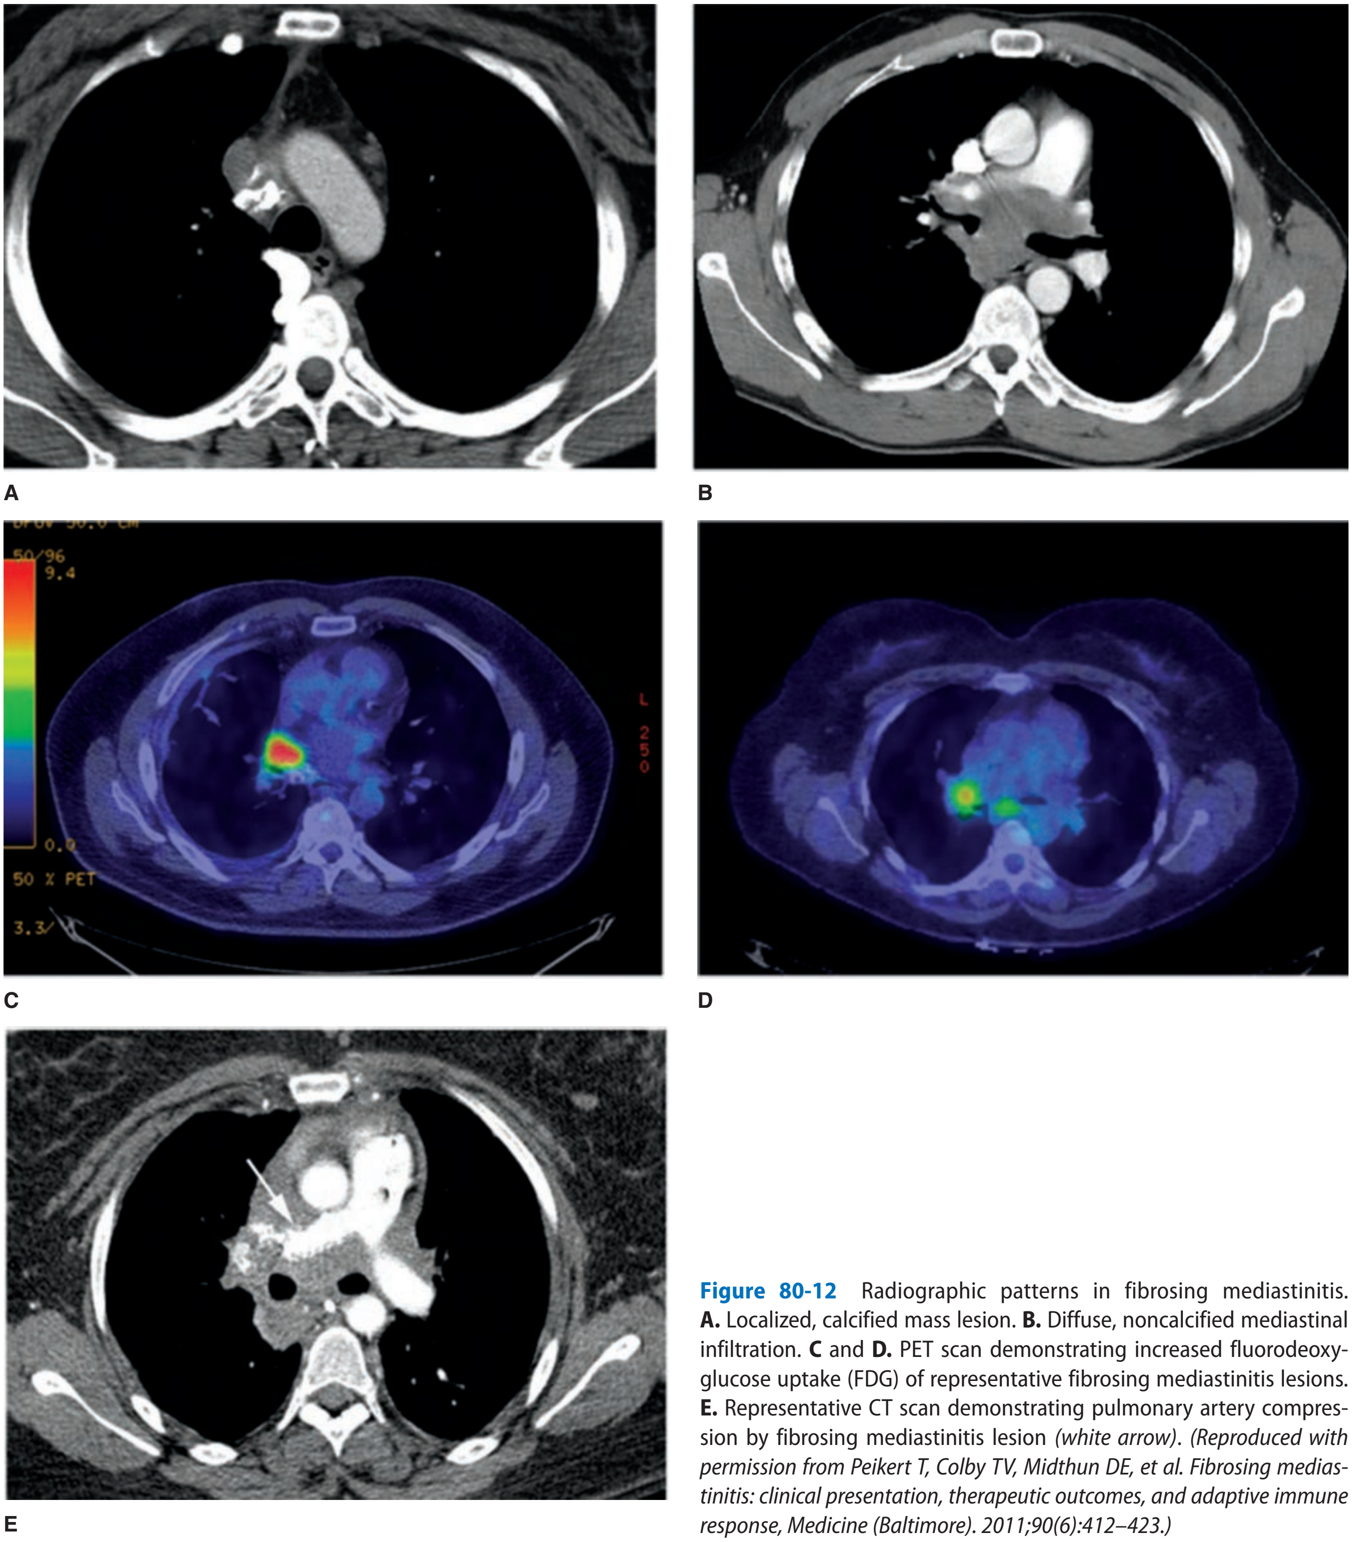

Figure 80-12 Radiographic patterns in fibrosing mediastinitis. **A.** Localized, calcified mass lesion. **B.** Diffuse, noncalcified mediastinal infiltration. **C** and **D.** PET scan demonstrating increased fluorodeoxyglucose uptake (FDG) of representative fibrosing mediastinitis lesions. **E.** Representative CT scan demonstrating pulmonary artery compression by fibrosing mediastinitis lesion *(white arrow)*. *(Reproduced with permission from Peikert T, Colby TV, Midthun DE, et al. Fibrosing mediastinitis: clinical presentation, therapeutic outcomes, and adaptive immune response, Medicine (Baltimore). 2011;90(6):412–423.)*

adequate management of a compressed airway. A Y-bifurcation stent and individual self-expanding stents placed in the trachea or bronchi are available. Kern et al.[62] described the use of silicone stents in 7 patients with extrinsic central airway compression due to fibrosing mediastinitis (representing 5% of all patients with fibrosing mediastinitis during the study period). There were 3 cases of unilateral mainstem bronchus stenting, two of bilateral mainstem bronchus stenting, and two distal tracheal Y-stents. Repeat bronchoscopies to clear impacted secretions or remove granulation tissue were frequently required. In most cases, the airway stents remained in place for months to several years, but they were eventually removed in 5 of 7 patients. Airway management must be individualized based on findings at bronchoscopy. Often the airway strictures are so fibrotic that they are not amenable to stenting.[44]

Complete or partial unilateral or bilateral pulmonary artery obstruction can result from fibrosing mediastinitis (Fig. 80-12).[44,47,48] Dyspnea and signs of right heart failure can be present and the presentation can mimic that of idiopathic pulmonary arterial hypertension or chronic pulmonary thromboembolism. The fibrosis may also extend to involve the pulmonary veins, producing a syndrome mimicking pulmonary veno-occlusive disease. Involvement of multiple pulmonary veins is frequent given their proximity. Surgical correction of these disorders is rarely possible due to the extreme fibrosis present around the vessels. Angioplasty and/or stenting of the pulmonary arteries and veins has been reported. Albers et al.[61] reported stenting of 26 pulmonary arteries in 19 patients with improved vessel diameter and concomitant decrease in PA systolic pressure gradients. Only 1 (5%) patient required reintervention due to restenosis of a PA stent. Another study of 9 patients[63] documented a 90% patency rate of pulmonary artery stents at 1 year. Complications from pulmonary artery endovascular interventions include vessel injury with complete occlusion, reperfusion pulmonary edema, and thrombosis requiring anticoagulation. Endovascular intervention is also possible in cases of pulmonary vein involvement, although restenosis rates of 25% to 50% and a 1-month mortality rate of 38% have been reported.[61,64] Complications from pulmonary vein endovascular interventions include pulmonary hemorrhage with hemoptysis, vessel dissection or rupture, and systemic embolic events. If the situation is unilateral with associated airway obstruction, a pneumonectomy may be an alternative.

Esophageal obstruction resulting from fibrosing mediastinitis most frequently involves the middle third of the esophagus because of its relationship to the subcarinal space. Dilation, enucleation of scar, and resection are therapeutic options. Fistulas may occur between the subcarinal lymph nodes and the esophagus or into the tracheobronchial tree. Operative treatment for fistula formation is directed at closing the fistula and separating the airway and esophagus using viable tissue such as muscle. An esophageal diverticulum may form from inflammatory adherence to the subcarinal lymph nodes but is usually asymptomatic (Fig. 80-10).

Beyond the palliative interventions for compression of vital mediastinal structures described above, the optimal treatment of fibrosing mediastinitis remains unknown. Case reports have suggested that antifungal, anti-inflammatory, or antifibrotic treatment may have some benefit, but large case series mostly refute these observations. Westerly et al.[65] reported on the successful use of rituximab, an anti-CD20 monoclonal antibody targeting B lymphocytes, in three patients with mediastinal fibrosis with improvement of symptoms and a reduction in size and metabolic activity of the fibrotic lesions on imaging after B cell depletion.

Peikert et al.[45] from the Mayo Clinic reviewed one of the largest series comprising 80 patients with fibrosing mediastinitis that nicely summarizes our current understanding of this disease. Their clinical definition of fibrosing mediastinitis was radiographic evidence of an infiltrative mediastinal process with associated vascular, airway, or esophageal compression. The pathologic definition was that of a predominance of extensive paucicellular fibrotic tissue infiltrating and obliterating adipose tissue with or without patchy infiltration of mononuclear cells. The median age at presentation was 42 years with an equal gender distribution. There was evidence of histoplasmosis (by culture, fungal stains, or positive serologic titer) in 83% of patients. The involved mediastinal organs that were compressed were vascular (48%), bronchial (27%), superior vena cava only (20%), and esophagus (3%). Only 5% of patients were asymptomatic at presentation. Presenting symptoms included dyspnea (47%), cough (21%), symptoms compatible with the superior vena cava syndrome (21%), chest pain (20%), and hemoptysis (20%). Focal mediastinal abnormalities on chest CT were seen in 95% of patients, while diffuse mediastinal infiltration was seen in 5%. Calcifications were seen in 73% of patients. PET scans, when obtained for the suspicion of malignancy, were uniformly positive. Medical therapy with antifungal treatment was minimally effective, with only an 18% rate of a partial response. Endovascular interventions were successful in 11 of 13 patients with vascular compression; however, the majority required repeat interventions for stent stenosis. Bronchoscopic balloon dilatation of stenotic airways was performed in 2 patients but failed to produce symptomatic relief in either case. Surgical interventions were successful in 16 of 17 patients (94%). These included bypass of the SVC with a spiral vein graft (3 patients) or polytetrafluoroethylene graft (2 patients), anatomic lung resections to control hemoptysis (4 patients), bronchoplasty or decompression of the airway (3 patients, 1 unsuccessful), pulmonary artery bypass (2 patients), decompression or enlargement of the pulmonary veins (2 patients), and decompression of the esophagus (1 patient). There were no periprocedural deaths. Long-term survival of these patients was identical to that of age-matched controls.

SPONTANEOUS MEDIASTINAL HEMORRHAGE

Mediastinal hemorrhage is usually due to aortic dissection, contained rupture of a thoracic aortic aneurysm, trauma, or iatrogenic injury. Spontaneous mediastinal hemorrhage is extremely rare. Although it can occur in otherwise healthy patients, spontaneous mediastinal hemorrhage has been reported in patients with bleeding diathesis, such as patients with end-stage renal disease on chronic dialysis or those on anticoagulation.[66–68] Symptoms are usually of sudden onset and consist of substernal pain, dyspnea, and, rarely, hemodynamic compromise. The hemorrhage is usually brief and self-limited. Treatment is supportive, and secondary causes of mediastinal hemorrhage must be excluded. Mediastinal fibrosis has rarely been reported following mediastinal hemorrhage.

CHAPTER 81

Congenital Cysts of the Mediastinum: Bronchopulmonary Foregut Anomalies

Erik E. Lewis
Daniel P. McCarthy
Malcolm M. DeCamp

INTRODUCTION

Mediastinal masses encompass a diverse spectrum of solid tumors, vascular abnormalities, and cysts, arising from and associated with each of the structures found within the mediastinum.[1–4] Cystic lesions account for up to 25% of reported mediastinal masses.[1,3–5] These cysts may be congenital or acquired, or they may represent cystic degeneration of a previously solid tumor. In this chapter, we focus on congenital cystic lesions within the mediastinum, specifically addressing foregut cysts including bronchogenic cysts, enterogenous (esophageal duplication) cysts, and neurenteric cysts. Together, they constitute up to 9% of all primary mediastinal masses. We will also briefly consider simple cysts arising from the thymus, pericardium, and thoracic duct. Many other solid mediastinal neoplasms (dermoids, teratomas, thymomas, parathyroid adenomas, and thyroid goiters) may present with cystic components. These lesions are discussed separately in Chapter 82.

ANATOMY

Cysts may arise in each of the three anatomic compartments of the mediastinum. The boundaries of these compartments, based on cross-sectional imaging, were recently codified by the International Thymic Malignancy Interest Group, with small but significant changes to previous descriptions.[6–9]

The *prevascular compartment* is bounded superiorly by the thoracic inlet, inferiorly by the diaphragm, laterally by the parietal mediastinal pleura, anteriorly by the sternum, and posteriorly by the anterior aspect of the pericardium, as it wraps around the heart and vessels in a curvilinear fashion. Thymic cysts and endocrine lesions, such as thyroid goiters and cystic adenomas of the parathyroid gland, are found in this compartment.[6,7]

The *visceral compartment* is the site of origin of most congenital foregut cysts. The boundaries of the visceral compartment include the thoracic inlet superiorly and the diaphragm inferiorly. The anterior border is the anterior aspect of the pericardium as it wraps around the heart and vessels in curvilinear fashion. The posterior border is defined as a vertical line transecting each thoracic vertebrae 1 cm posterior to its anterior margin. Bronchogenic cysts, enterogenous cysts, pericardial cysts, and thoracic duct cysts arise in this compartment.[6,7]

The *paravertebral compartment* also extends from the thoracic inlet superiorly to the diaphragm inferiorly. The anterior border is the “visceral-paravertebral compartment boundary line” (1 cm posterior to the anterior margins of the vertebrae). The posterolateral margin is defined as the vertical line against the posterior margin of the chest wall at the lateral margin of the transverse processes of the thoracic spine. The paravertebral compartment includes both costovertebral sulci and segmental nerve roots, as well as the sympathetic chain and paravertebral soft tissues. Neurenteric cysts arise within this compartment.[6,7]

It is important to note that lesions that arise primarily within the mediastinum may also extend above the chest into the neck or below the diaphragm into the retroperitoneum, where they present as extrathoracic mass lesions. In addition, cysts within one mediastinal compartment may also extend into the adjacent compartment, since there are no strict anatomic barriers.

EPIDEMIOLOGY

In published series of mediastinal masses, the prevalence of primary cysts ranges from 10% to 25% and has remained steady for the past seven decades (Table 81-1) with relatively similar incidences in males and females. Some minor heterogeneity over this time span is accounted for by variations in the ages of patients reported in each series.[1,3–5,11–13]

Bronchogenic cysts account for approximately 40% of mediastinal cysts, while pericardial cysts account for 35%, enteric for 10%, and nonspecific cysts for 15%. The etiology and distribution of cystic mediastinal masses are different in children and adults. Cysts of foregut origin account for only half of the lesions found in adults, whereas they constitute nearly 90% of cystic lesions reported in pediatric series (Table 81-2). Conversely, pericardial cysts account for up to one-third of all cystic lesions in adults, whereas true pericardial cysts are

exceedingly rare in children. Among congenital lesions of the foregut and tracheobronchial tree seen in children—including pulmonary sequestrations, congenital lobar emphysema, cystic adenomatoid malformations, arteriovenous malformations, and bronchial atresias—simple foregut cysts (bronchogenic, enterogenous, and neurenteric) constitute between 13% and 29% of reported cases.[4,5,11–14]

Although the relative frequencies of cystic and solid mediastinal masses have remained fairly constant, the advent of cross-sectional imaging techniques, such as computed tomography (CT) and magnetic resonance imaging (MRI), has substantially increased the detection of all mediastinal lesions.[15–19]

Multidetector computed tomography (MDCT) with volumetric acquisition provides fast acquisition of high-resolution images and multiplanar reconstructions. Both two-dimensional and three-dimensional imaging may help with improving diagnostic accuracy, surgical planning, and assessing resectability preoperatively. In most cases, CT imaging provides enough information to make accurate diagnostic and therapeutic decisions without further testing. In selected cases, MRI may offer advantages over other modalities for detecting and identifying cystic, or fluid-filled mediastinal masses, because of the intrinsic high soft tissue contrast and direct multiplanar imaging capabilities. Regardless of the modality, sagittal or coronal reformations can provide invaluable anatomic information that the transaxial images may not.

BRONCHOGENIC CYSTS

The embryology, clinical presentation, diagnosis, and management of bronchogenic cysts are discussed below.

Embryology and Terminology

The primitive respiratory and upper gastrointestinal systems have a common embryologic endodermal origin. The primitive foregut gives rise to a variety of aerodigestive organs and tissues, beginning with the pharynx and subsequently giving rise to the larynx, upper and lower respiratory tracts, esophagus, stomach, proximal duodenum, liver, pancreas, and associated ducts.[20] Cystic malformations of foregut origin may have a variety of epithelial linings that reflect the embryologic tissues from which they are derived. The lung bud develops caudally from the laryngotracheal tube, beginning in the fourth week of gestation. By the fifth week, the single bud has divided into right and left main bronchi, which grow into the surrounding splanchnic mesenchyme that is destined to become bronchial cartilage and smooth muscle as well as visceral pleura. Dichotomous branching of the primitive bronchi continues until about the 24th week, when the terminal bronchioles begin to give rise to primitive alveoli.

Throughout this period of embryogenesis, abnormal bronchi and bronchioles may form larger saccular structures, which are clinically recognized as bronchogenic cysts. Such saccular malformations may be invested by their own splanchnic mesenchyme (neopleura). Abnormal bud separation may lead to cyst formation lined with respiratory epithelium. Some investigators believe that mediastinal bronchogenic cysts arise early in the cycle of bronchial branching, whereas intrapulmonary bronchogenic cysts represent derangements occurring later in fetal development. If the separation occurs early, the cyst is associated with the large airways within the mediastinum, whereas delayed bud separation may lead to cyst formation more distally within the lung parenchyma. Approximately three-quarters of bronchogenic cysts are within the mediastinum and associated with the large airways and one-quarter are intraparenchymal.[19] Cysts abutting the trachea, carina, or hilum are termed *mediastinal bronchogenic cysts*; they rarely maintain communication with the respiratory tract (Figs. 81-1 and 81-2). Less frequently, these lesions are contained within the pulmonary parenchyma, most commonly in the lower lobes and are termed

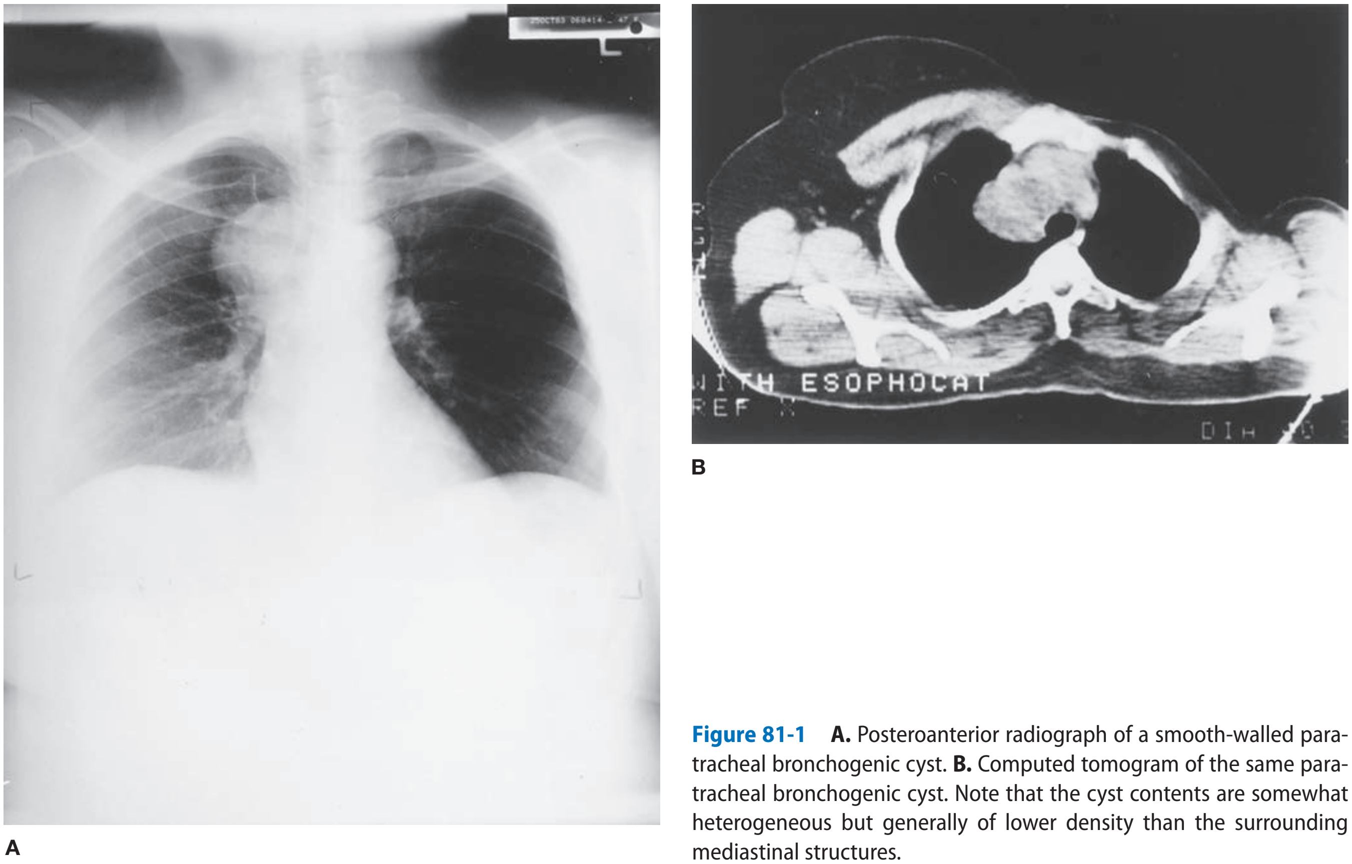

Figure 81-1 **A.** Posteroanterior radiograph of a smooth-walled paratracheal bronchogenic cyst. **B.** Computed tomogram of the same paratracheal bronchogenic cyst. Note that the cyst contents are somewhat heterogeneous but generally of lower density than the surrounding mediastinal structures.

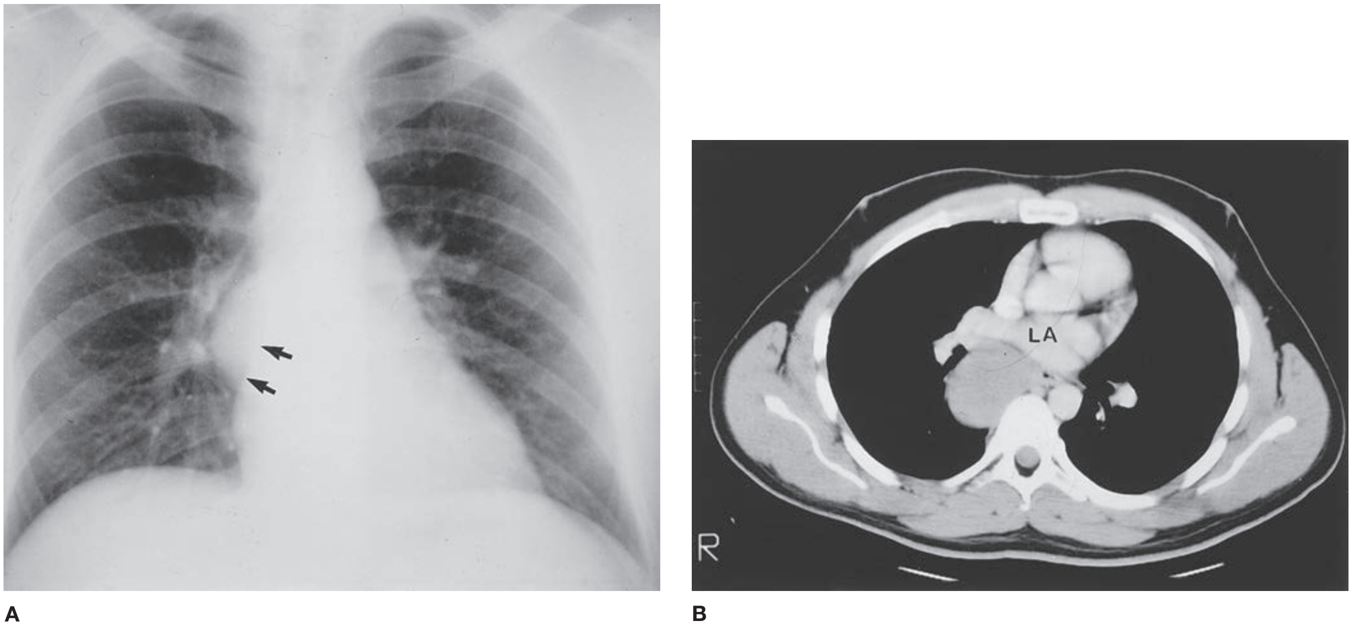

Figure 81-2 **A.** Posteroanterior radiograph of a smooth-walled subcarinal bronchogenic cyst. Note that the cyst is distinct from the right heart border *(arrows)*. **B.** Contrast-enhanced axial CT image of the homogeneous, subcarinal bronchogenic cyst. This patient presented with atrial dysrhythmia attributed to left atrial *(LA)* compression by the cyst. *(Reproduced with permission from Baue AE, Geha AS, Hammond GL, et al. Glenn's Thoracic and Cardiovascular Surgery, 6th ed. Stamford, CT: Appleton & Lange; 1996.)*

intrapulmonary bronchogenic cysts (Fig. 81-3). Other locations include the neck, esophageal wall, pleura, diaphragm, and, rarely, the skin. Bronchogenic cysts are lined by respiratory epithelium and may contain cartilage within their walls. Because they uniformly arise before alveoli form (at 28 weeks), bronchogenic cysts have no gas exchange potential even if their bronchial communications persist, an extremely rare event.

■ Presentation and Diagnosis

Bronchogenic cysts are the most frequent cystic lesions found in the mediastinum and represent up to 15% to 20% of all mediastinal masses. The majority of mediastinal bronchogenic cysts are located below the carina (77%), while the remainder occur above the carina (23%). Most young patients with bronchogenic cysts have symptoms at the time of diagnosis (Table 81-3), although in a significant minority of patients (20%–30%), the cysts may be identified incidentally on CT scans performed for other reasons. The pediatric population is particularly predisposed to symptomatic cysts due to the smaller size of their thorax and more malleable airways.[1,5,11,13] Eraklis et al. noted life-threatening respiratory compromise in 70% of infants with foregut cysts.[21] Mass effects from the cysts, which caused compression, "ball valving," or differential ventilation, were the predominant causes of respiratory distress. These neonates were often cyanotic, with wheezing or stridor, and their radiographs

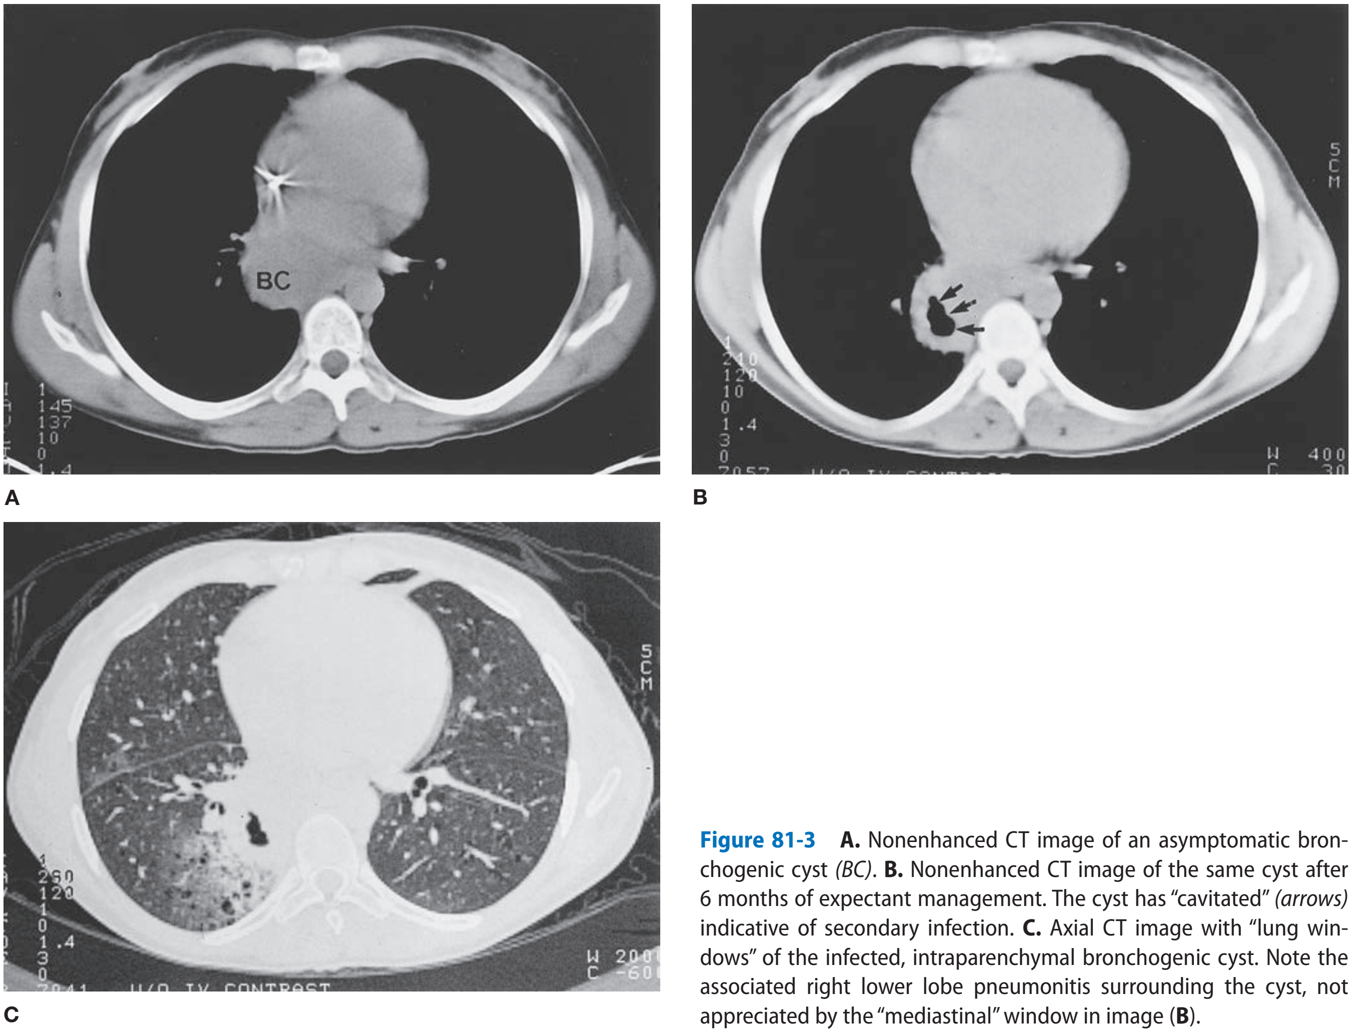

Figure 81-3 **A.** Nonenhanced CT image of an asymptomatic bronchogenic cyst *(BC)*. **B.** Nonenhanced CT image of the same cyst after 6 months of expectant management. The cyst has "cavitated" *(arrows)* indicative of secondary infection. **C.** Axial CT image with "lung windows" of the infected, intraparenchymal bronchogenic cyst. Note the associated right lower lobe pneumonitis surrounding the cyst, not appreciated by the "mediastinal" window in image (**B**).

demonstrated inhomogeneous aeration, lobar collapse, and/or mediastinal shift. In published series of non-neonatal children, up to 95% had symptoms. Signs and symptoms of infection may be present, especially in the older children.

In adults, symptomatic bronchogenic cysts are less common.[1,4,13,22,23] In a large series, symptoms were present in about one-third of patients and included chest pain, cough, wheezing, stridor, dyspnea, dysphagia, cyanotic spells, and pneumonia. Other manifestations include compression of the superior vena cava or left atrium, or evidence of infection such as pneumonia or empyema (Fig. 81-3C). In more recent series, 75% to 95% of patients were asymptomatic when the lesions were detected.[23–27] With long-term follow-up, however, two-thirds of patients who were initially asymptomatic eventually developed symptoms.

The presence of a bronchogenic cyst is suggested by plain chest radiographs in up to two-thirds of cases in any age group. The usual appearance is that of a 2- to 10-cm ovoid, smooth, homogeneous mass that abuts the mediastinum or hilum or splays out the carina.[28] An air–fluid level connotes either persistent bronchial communication or secondary infection of the cyst (Fig. 81-3). As mentioned earlier, some cysts (especially in infants) may exert a mass effect, causing airway compression, parenchymal atelectasis, or cardiovascular compression (Fig. 81-2B). In 60% to 65% of patients, posteroanterior and lateral plain chest radiographs make it possible to diagnose these lesions and to document their precise location.

Ultrasonography is helpful in confirming the cystic nature of mediastinal lesions in infants and children. Prenatal diagnosis also is feasible. Such forewarning allows for the expeditious management of these infants antenatally or at the time of delivery when most affected infants quickly develop symptoms coincident with inflation of the lungs. In the adult, surface ultrasonography has little to offer in the acoustic visualization of suspected bronchogenic cysts because air within the lungs is a poor conductor of sound. Endoscopic ultrasound can be useful in the diagnosis of mediastinal bronchogenic cysts, but needle aspiration through the esophagus should not be performed due to the possibility of infection and sepsis.[29,30]

Cross-sectional imaging techniques, using either CT or MRI, have become the diagnostic procedures of choice for investigating mediastinal masses. These methods provide helpful details of cyst structure, including the density and type of cystic fluid, amount of calcium in the cyst wall, vascularity of the cyst, and the relationships of the cyst to adjacent mediastinal structures. MRI and CT are probably equally useful in the diagnosis of mediastinal-based cysts, although in most situations a CT scan will provide all the necessary information. CT is superior for the examination of intrapulmonary cysts because of its ability to delineate more sharply the cystic lesion from the surrounding air-filled parenchyma (Figs. 81-1–81-3). On CT, bronchogenic cysts appear as a single, smooth, round, or elliptical mass with a well-defined, thin, smooth wall and nonenhancing homogeneous cyst mass. Half of these lesions have the same density as water with attenuation values in a range consistent with serous fluid (0–20 Hounsfield units [HUs]), and others have a CT density that varies depending on the cyst's protein content.[18,19,28] Higher attenuation in the range of 30 to 130 HU is the result of the presence of calcium, proteinaceous fluid, mucus, and/or blood within the cyst. The presence of especially high-attenuation fluid within the cyst on CT scan suggests a high calcium content (milk of calcium).[19] On MRI, bronchogenic cysts frequently show signal intensity higher than that of muscle on T1-weighted images. Variable signal intensity may be due to variable cystic components and presence of protein, blood, or mucoid material. On T2-weighted images, cysts show high signal intensity.

Bronchoscopy is normal in most cases, but abnormalities include extrinsic compression of the airways, secretions from infected cysts, and, rarely, direct communication with the cyst cavity. Rupture into the airway, esophagus, or pericardium also has been documented.

■ Therapy

The treatment options for bronchogenic cysts include observation, resection, and aspiration. In the absence of definitive diagnosis, surgical exploration is recommended for nearly all patients with an abnormal mediastinal mass. Bronchogenic cysts are the most commonly treated mediastinal foregut anomaly and account for 60% of all mediastinal masses. Once a bronchogenic cyst is diagnosed, surgical excision is indicated to relieve clinical symptoms, to address enlarging cysts, or to prevent possible complications including infection, malignant transformation, tracheal or vascular compression, or hemoptysis.[31–33] Complete excision of the cyst should be performed, thus minimizing the chance of recurrence and the potential for complications.

The techniques used for resection have evolved over time, but the fundamental principle of complete resection remains the same. Traditionally, a thoracotomy was necessary. Since most cysts are located in the subcarinal area, a right fifth interspace thoracotomy is usually recommended. With this technique, the right lung is mobilized anteriorly, and access is gained to the area below the azygos vein. The mediastinal pleura is incised, and the cyst is meticulously dissected free from the surrounding structures, with particular attention paid to the areas of attachment to the airway, esophagus, and pericardium. Over the last two decades, minimally invasive techniques utilizing video-assisted thoracoscopic surgery (VATS) with or without robotic assistance have been utilized with increasing frequency to resect mediastinal cysts with excellent results, low conversion rates to open procedure, and no significant increases in recurrence rates.[34–39] Multiple port configurations can be utilized for both VATS and robotic-assisted cases, with variations depending on the approach used and surgeon preference. Minimally invasive techniques allow less surgical trauma while adhering to the core principles of surgical management. The robotic platform has several theoretical strengths in addressing these lesions. Subcarinal bronchogenic cysts can extend to the mid or distal left main bronchus and may be densely adherent to the airway or esophagus, in a narrow and deep operative field. The robotic platform's three-dimensional magnified viewing system facilitates excellent visualization in hard-to-reach areas. In addition, the wristed instrumentation allows precise dissection along multiple trajectories even in a small and deep operative field.[39] As with open surgery, decompression of the cystic lesion by aspiration of its contents may sometimes facilitate handling and dissection.[36]

Additionally, there are other techniques that may be used for certain, specific circumstances. Urschel and Horan[40] described piecemeal resection of a mediastinal bronchogenic cyst using a Carlens mediastinoscope, introduced through a small suprasternal incision. This may be particularly helpful in the treatment of recurrent subcarinal cysts previously approached through a thoracotomy.

In some cases, full cyst resection is not possible. Partial resection of a bronchogenic cyst may occasionally be necessary, if the cyst is found to be densely adherent to and inseparable from the membranous airway, main pulmonary vessels, esophagus, phrenic nerve, or aorta. In these cases, most of the wall of the cyst should be excised and the mucosa lining the remaining cyst wall should be ablated with electrocautery, in an effort to prevent recurrences. When subtotal excision is necessary, symptomatic recurrences requiring re-excision have been reported.

Aspiration of a cyst to confirm a benign diagnosis and to instill a sclerosing agent (ethanol or bleomycin) has been used to manage some cysts in lieu of surgery. The advent of endobronchial ultrasonography with transbronchial intervention has resulted in an even less invasive management option. However, the fluid is almost always thick and viscous and unlikely to be drained through a long, small needle. Reports of long-term follow-up for this approach to both the diagnosis and therapy of bronchogenic cysts are scant. However, it may represent a useful form of therapy for inoperable patients.

Whatever the operative approach, the goal of surgery should be complete excision of all elements of the cyst. Occasional case reports of malignancy arising from the cyst mucosa support the general concept of complete resection for any bronchogenic cyst.[41] A variety of tumors have been associated with bronchogenic cysts including adenocarcinoma, squamous cell carcinoma, carcinoid tumors, anaplastic carcinoma, and leiomyosarcoma in both children and adults.

Treatment of asymptomatic cysts remains controversial.[42] A conservative approach can be considered for small, asymptomatic cysts that do not compress adjacent structures, do not enlarge over time, do not display atypical characteristics, and do not arouse any suspicion of malignancy.

ENTEROGENOUS (ESOPHAGEAL DUPLICATION) CYSTS

The embryology, clinical presentation, diagnosis, and management of enterogenous cysts are discussed below.

■ Embryology and Terminology

Enterogenous cysts are also termed *esophageal duplications*. They arise from the elongating esophagus, which separates from the respiratory tract at about the fifth week of gestation (see Chapter 4). As with most intestinal duplications, enterogenous cysts represent failure of normal recanalization during embryogenesis.[43] Most esophageal duplications are of the closed and cystic type. Rarely are they tubular or demonstrate preserved communication with the alimentary tract.

■ Presentation and Diagnosis

After leiomyomas and benign polyps, esophageal cysts are the third most common esophageal mass, although they remain much less common than bronchogenic cysts. Of all mediastinal cysts, only 5% to 15% are esophageal in origin. The majority of esophageal duplication cysts occur in infants or children, and nearly 75% of esophageal duplication cysts are recognized before 16 years of age.[44–46] In up to 60% of patients they are located adjacent to or within the lower one-third of the esophageal wall in the lower visceral mediastinum with a two-to-one predilection for cysts to be on the right side. Most adults are asymptomatic, with cysts incidentally identified on chest CT.[47] The natural history of esophageal cysts is variable, but if left untreated most will become symptomatic. Symptoms are usually due to compression of the airways resulting in cough, dyspnea, and occasionally stridor.[48–50] Dysphagia is surprisingly infrequent. In asymptomatic patients, the most common clue leading to this diagnosis is the coexistence of other gastrointestinal duplication(s). Associated conditions include other intestinal cysts, esophageal atresia, tracheoesophageal fistula, and spinal abnormalities. Unlike bronchogenic cysts, which are always lined with respiratory mucosa, enterogenous cysts may have a variety of epithelial linings, including the squamous epithelium native to the esophagus. From 50% to 60% of esophageal cysts contain ectopic gastric mucosa, with some containing pancreatic tissue. The presence of gastric mucosa containing parietal cells capable of acid secretion may explain events such as spontaneous hemorrhage and perforation.[49]

Esophageal duplications usually present radiographically as smooth-walled, visceral mediastinal lesions at the base of the right hemithorax (Fig. 81-4A). A barium swallow demonstrates deviation of the lumen around the cyst but rarely shows communication with it (Fig. 81-4B). Proximal esophageal dilatation is not common because the cysts usually are not obstructive. In patients with suspected duplication, a technetium pertechnetate nuclear scan may suggest the presence of ectopic gastric mucosa within the chest. Cross-sectional imaging (CT or MRI) is routinely employed to characterize the contents of a cyst and to define the relationship of the cyst to contiguous structures (Fig. 81-4C). The characteristic CT and MRI findings are identical to those of bronchogenic cysts, except that the wall may be thicker and in closer contact with the esophagus. Endoesophageal ultrasound has provided a useful, minimally invasive tool to investigate these lesions and to allow sampling of cyst contents to confirm that the lesion, in an otherwise asymptomatic patient, is benign.[29,51] There is, however, potential risk of infection and aspiration should be avoided if the echo characteristics suggest a simple cyst. Esophagoscopy, when performed, will demonstrate a smooth, soft, compressible mass without mucosal abnormality or communication with the extraluminal mass.

■ Therapy

As in the case of bronchogenic cysts, esophageal duplications are likely to become larger or infected over time. Thus, resection is recommended for all enterogenous cysts, whether for current symptoms or for the high likelihood of future complications. Esophageal

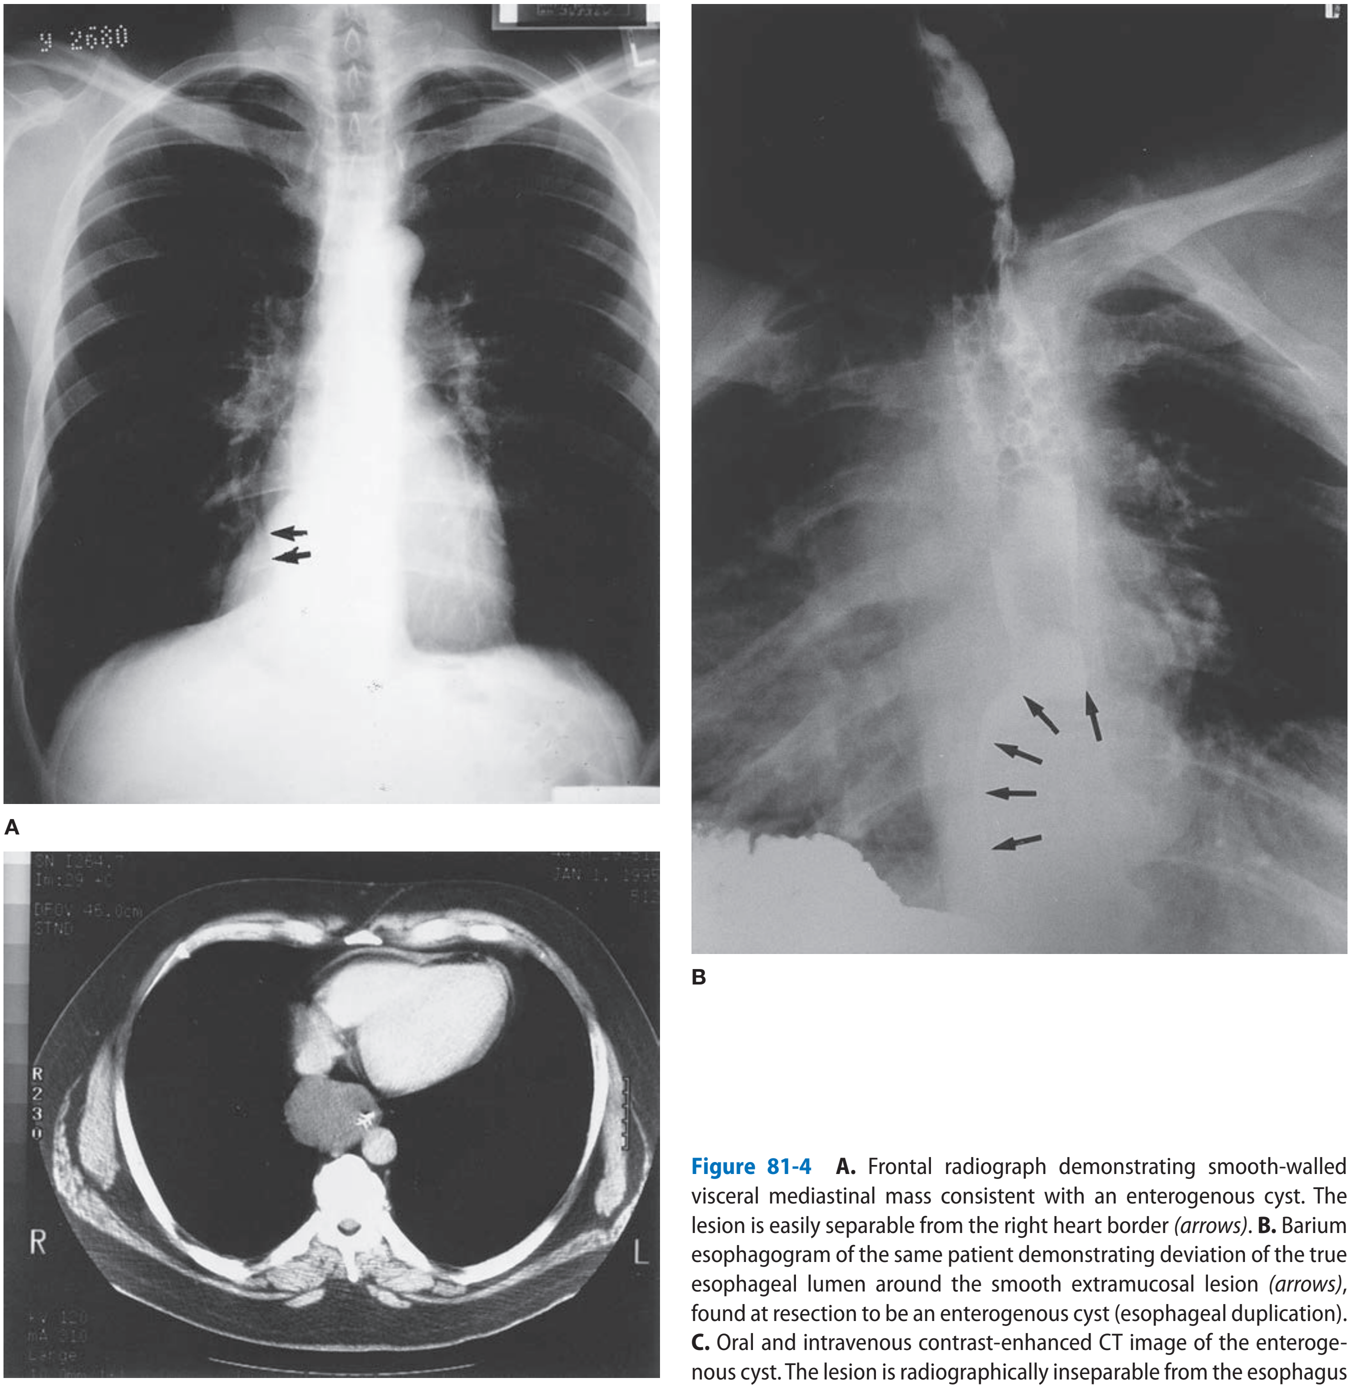

Figure 81-4 **A.** Frontal radiograph demonstrating smooth-walled visceral mediastinal mass consistent with an enterogenous cyst. The lesion is easily separable from the right heart border *(arrows)*. **B.** Barium esophagogram of the same patient demonstrating deviation of the true esophageal lumen around the smooth extramucosal lesion *(arrows)*, found at resection to be an enterogenous cyst (esophageal duplication). **C.** Oral and intravenous contrast-enhanced CT image of the enterogenous cyst. The lesion is radiographically inseparable from the esophagus but free of all cardiac structures.

duplication cysts can be approached through a standard thoracotomy, VATS, or robotic techniques.[52–58] Regardless of the approach, the following steps should be emphasized: (1) preservation of the muscular layer for repair, (2) identification and preservation of the vagus nerves, and (3) assessment of mucosal integrity via air insufflation under water. In most cases a plane of dissection in the submucosa can be achieved to complete the resection. Despite the lack of communication with the esophageal lumen, cyst resection may leave defects in the esophageal wall that must be meticulously repaired. If the mucosa is breached, the esophagus should be closed primarily in layers, and the repair should be reinforced with a locally procured flap of vascularized tissue. Options for buttressing include the pericardial fat pad, pleura, intercostal muscle, pericardium, or omentum. Case reports documenting the occurrence of an adenocarcinoma in esophageal duplication cysts underscore the need for resection at the time of diagnosis.

NEURENTERIC CYSTS

The embryology, clinical presentation, diagnosis, and management of neurenteric cysts are discussed below.

Embryology and Terminology

During the third week of normal embryogenesis, the notochord should separate from the primitive foregut (see Chapter 4). If this separation is incomplete, the mesodermal masses, which normally encircle the neural tube, cannot enclose it and vertebral anomalies arise. The attached foregut often spawns an associated mediastinal enteric cyst. This form of congenital cyst accounts for only 5% to 10% of all foregut lesions and is consistently associated with bony anomalies of the spine.[59] The spectrum of vertebral anomalies includes butterfly vertebrae, hemivertebrae, and anterior spina bifida. They occur primarily in the lower cervical and upper thoracic regions and are usually cephalad to the cystic lesion, since the esophagus descends (or the pharynx ascends) during fetal development. The fluid within the cyst may be nearly identical to cerebrospinal fluid or may be milky, cream-colored, yellowish, or xanthochromic. Neurenteric cysts may be intradural, extramedullary, and situated ventral or ventrolateral to the spinal cord.[60]

Presentation and Diagnosis

Neurenteric cysts are exceedingly rare; virtually all present within the first year of life.[61] More than half of afflicted children have neurologic complaints or findings. These include back pain, motor deficits of a lower extremity, and gait disturbance, especially if there is communication with the spinal canal. Often the triad of a mediastinal mass, airway symptoms, and a vertebral anomaly will be present. The diagnosis is frequently made after detection of vertebral anomalies on the chest radiograph. CT scans show vertebral abnormalities in 50% of affected patients and can define bony abnormalities and demonstrate extension of the cystic lesion into the spinal canal. MRI has supplanted CT myelography and provides a complete, noninvasive assessment of the bony abnormality, the intraspinal extent of the cyst, and the degree of spinal cord or nerve root compression associated with a neurenteric cyst.[62]

Therapy

Careful imaging of suspected neurenteric cysts is paramount for successful extirpation. MRI is useful to exclude extension of the cystic component into a neural foramen or the spinal canal proper and to exclude an associated meningocele. Such findings would require a staged resection employing a posterior neurosurgical approach first, to decompress the cord or its nerve roots, followed by resection of the mediastinal component by standard thoracotomy or VATS.[62–65] Complete cyst excision is the treatment of choice. When preoperative diagnostic imaging shows no intraspinal extension of the cyst, thoracoscopic excision may be possible. When there is only minimal involvement of the vertebral body, resection can be accomplished with VATS or more commonly a posterolateral thoracotomy. If the

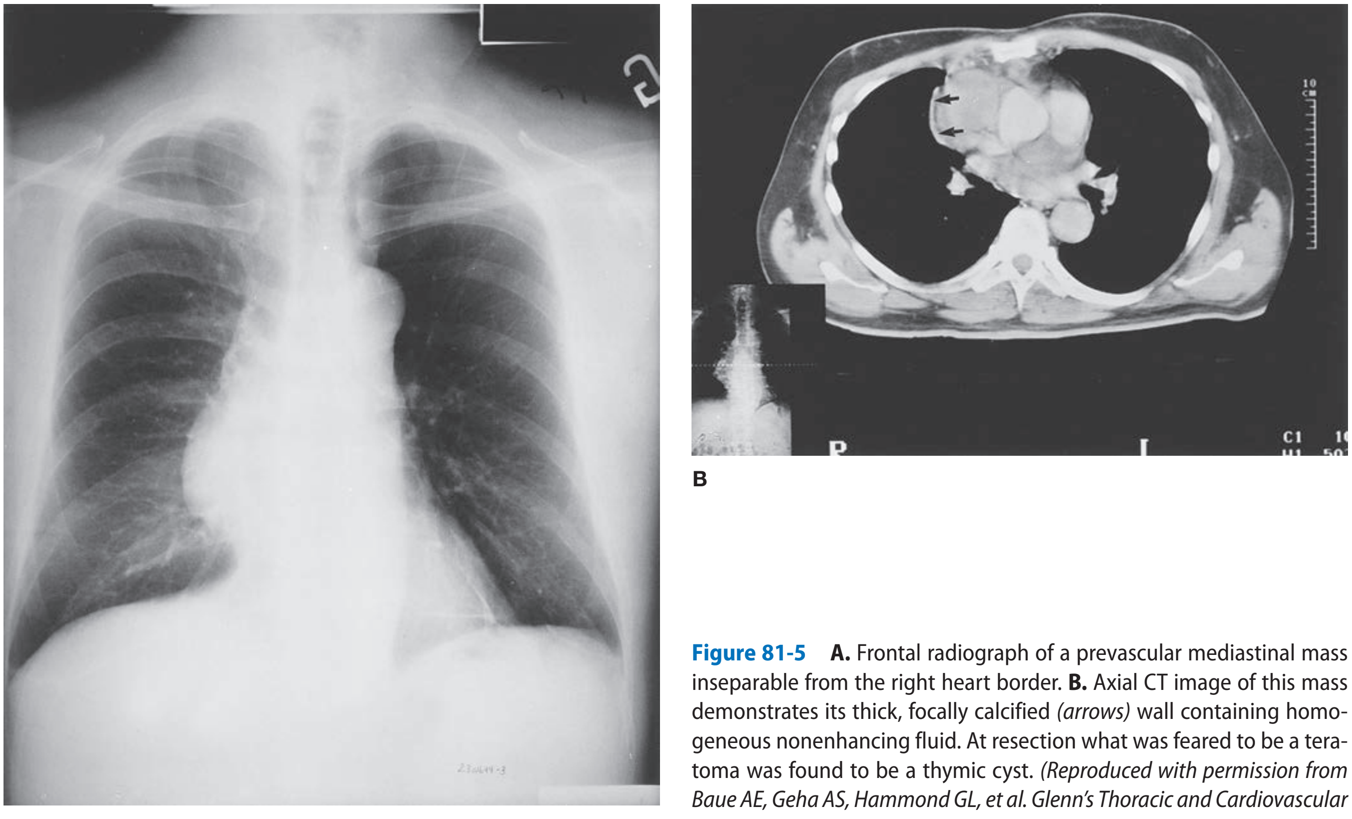

Figure 81-5 **A.** Frontal radiograph of a prevascular mediastinal mass inseparable from the right heart border. **B.** Axial CT image of this mass demonstrates its thick, focally calcified *(arrows)* wall containing homogeneous nonenhancing fluid. At resection what was feared to be a teratoma was found to be a thymic cyst. *(Reproduced with permission from Baue AE, Geha AS, Hammond GL, et al. Glenn's Thoracic and Cardiovascular Surgery, 6th ed. Stamford, CT: Appleton & Lange; 1996.)*

spinal abnormality is severe, a combined neurosurgical and thoracic approach is recommended.

THYMIC CYSTS

The thymus is derived from the third pharyngeal pouch. Its development is incomplete at birth, and the gland continues to grow throughout childhood into adolescence. Cysts within the gland are thought to occur during adulthood, when gland architecture involutes and central cells degenerate and are replaced by fat.

Thymic cysts are rare congenital or acquired lesions embryologically derived from the pharyngeal pouches. They account for only 3% to 5% of all prevascular mediastinal masses.[4–6,11,14,19] Most thymic cysts are asymptomatic and discovered incidentally on imaging studies performed for other reasons. Although thymic cysts are benign, they must be distinguished from thymomas, germ cell tumors, and lymphomas—all of which may have areas of cystic degeneration. These cysts arise in the prevascular compartment (Fig. 81-5) and may extend to the visceral compartment, especially in the aortopulmonary window (Fig. 81-6).[66] Congenital cysts are typically unilocular and contain clear fluid and an imperceptibly thin wall. Multilocular thymic cysts are usually acquired lesions. Plain radiographs do not differentiate thymic cysts from other non-lobulated thymic masses; therefore CT and MRI are employed for diagnosis. Both CT and MRI demonstrate clear tissue planes separating the cyst from other vital structures (Figs. 81-5 and 81-6). If hemorrhage or infection occurs, the cyst may show high signal intensity. In older patients, benign cysts may degenerate and present as a complex, thickened cystic mass with calcified walls that contain heterogeneous fluid (Fig. 81-5). Such lesions are easily confused with a mediastinal teratoma. Multiloculated thymic cysts can occur in association with thymic neoplasms, including thymoma and thymic carcinoma. Complete thymic excision can be accomplished through sternotomy, thoracotomy, VATS, or robotically.[36,37,56–58]

PERICARDIAL CYSTS

Pericardial diverticula and pericardial cysts represent slightly different stages of a lesion that has a common embryogenesis. When a communication exists between the pericardial sac and the extrapericardial fluid collection, the lesion is a diverticulum. Absence of communication defines a pericardial cyst.[67] Both diverticula and cysts derive from the ventral recess of the pericardial coelom, rather than from the pericardial lacunae. The discovery that a diverticulum-like structure in the ventral recess of the pericardial coelom occurred during development of the pericardium at the site

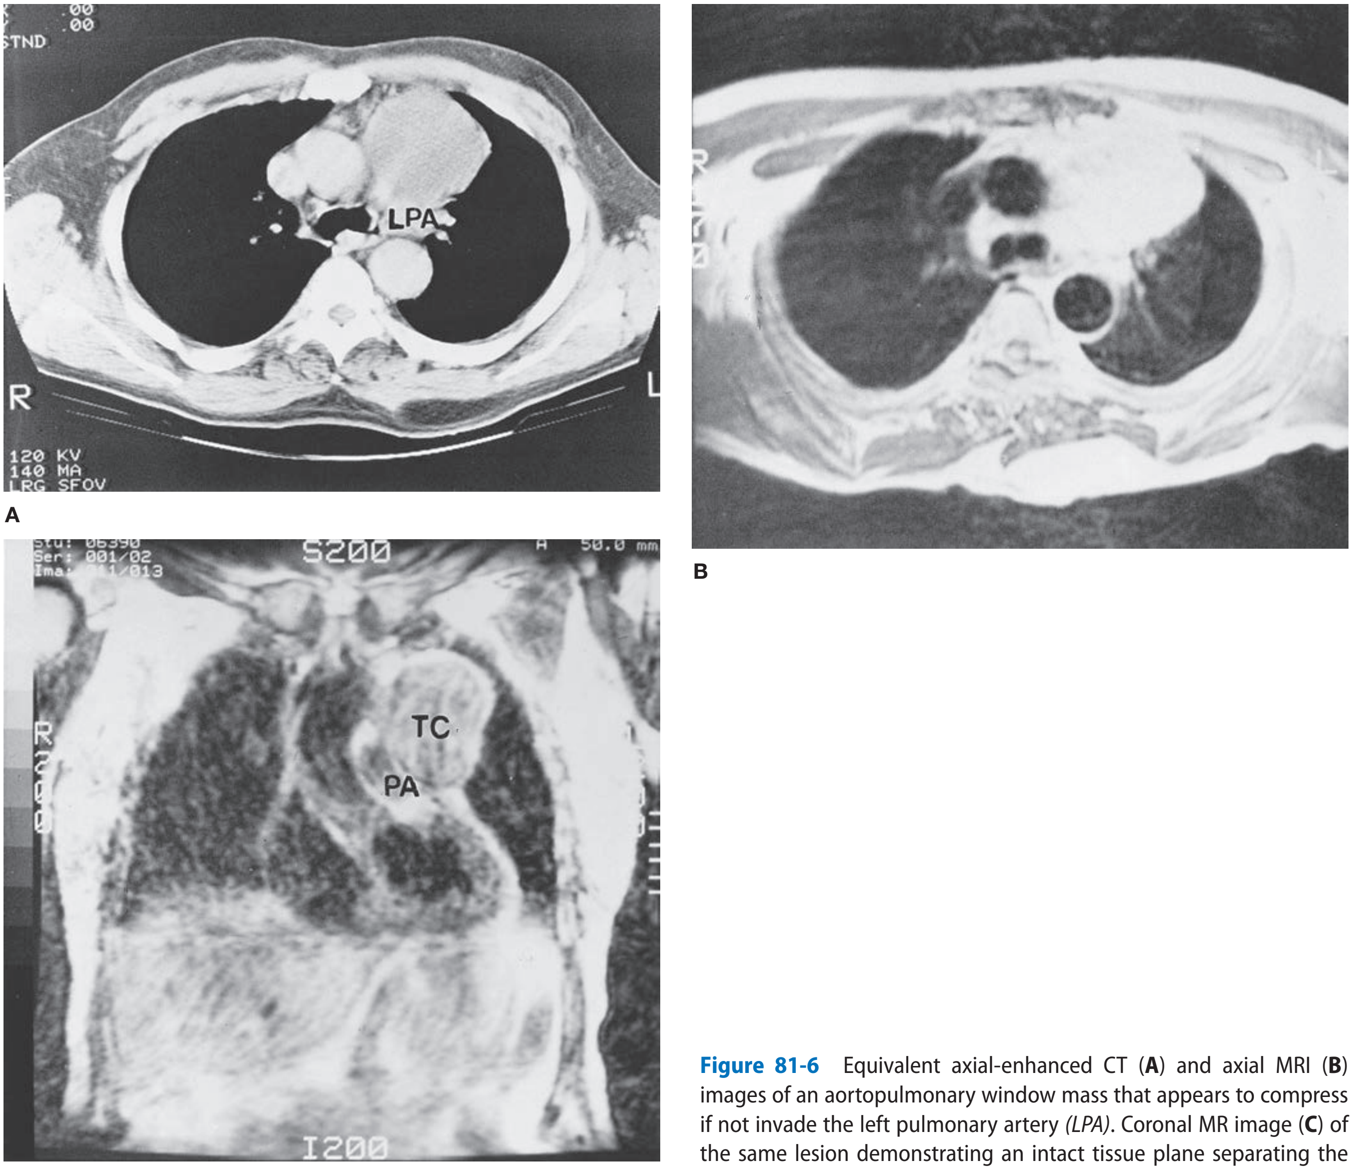

Figure 81-6 Equivalent axial-enhanced CT (**A**) and axial MRI (**B**) images of an aortopulmonary window mass that appears to compress if not invade the left pulmonary artery *(LPA)*. Coronal MR image (**C**) of the same lesion demonstrating an intact tissue plane separating the benign thymic cyst *(TC)* from the pulmonary artery *(PA)*.

where so many of these lesions were found led to speculation as to their possible relationship. Persistence of the recess results in formation of a diverticulum, while constriction of the proximal part of the persistent recess accounts for either a diverticulum with a narrow neck or a cyst in communication with the pericardial cavity. If the proximal portion of the recess is completely pinched off, an isolated pericardial cyst occurs in the cardiophrenic angle.

Pericardial cysts are simple, smooth-walled cystic lesions (Fig. 81-7) that are commonly located at the lateral basal edge of the pericardium, where it fuses with the diaphragm at the right cardiophrenic angle.[68] They can be mistaken for foramen of Morgagni hernias or prominent pericardial fat pads. They can be differentiated from more solid mediastinal tumors by CT or MRI. Pericardial cysts characteristically contain clear, low-density serous fluid. The appearance of these thin-walled, translucent cysts containing crystal-clear fluid gave rise to the term "spring water cysts."[64] They have no malignant potential and rarely get infected. Potential complications include hemorrhage or spontaneous rupture. Needle aspiration is often followed by reaccumulation of fluid and is not generally recommended. Surgery for pericardial cysts or diverticula is not indicated in the majority of cases, because these lesions are always benign, and most are asymptomatic. Resection should be reserved for cysts that cause symptoms (hemodynamic compromise, arrhythmia, chest discomfort, substernal pain, atelectasis) or for those demonstrating significant enlargement over time.[68] The operative approach, whether endoscopic or open, is dependent upon the location, size, and proximity of the cyst to vital structures. Most often, a right VATS approach is successful in excising the cyst. In most cases, standard two- or three-incision technique is utilized. Because pericardial cysts often overlie the right phrenic nerve, an unroofing procedure or subtotal resection is acceptable therapy if total excision would jeopardize diaphragmatic function.

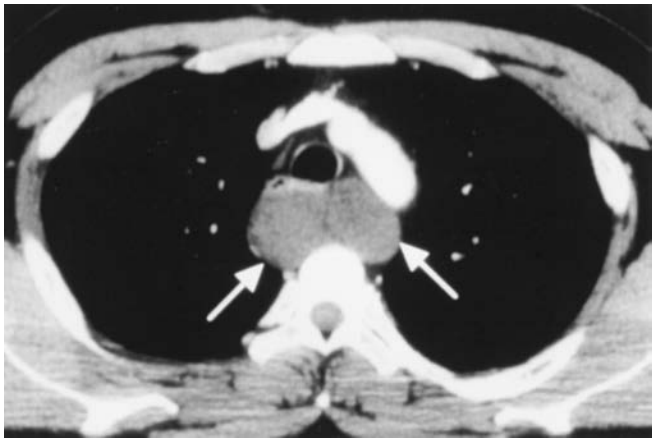

Figure 81-8 Axial contrast-enhanced CT scan of the chest revealed a large cystic mass measuring 3 × 5 × 15 cm *(arrows)*, displacing the esophagus and trachea anteriorly. *(Reproduced with permission from Chen F, Bando T, Hanaoka N, et al. Mediastinal thoracic duct cyst. Chest. 1999;115(2):584–585.)*

THORACIC DUCT CYSTS

Lymphatic channels develop from the lateral plate mesoderm, either as outgrowths of the venous system or by the fusion of mesenchymal clefts into vessels. The lymphatic sacs, which develop by the second month of gestation, are connected by these primitive lymphatic channels. It is these channels that unite the jugular lymph sacs to the cisterna chyli to form the thoracic duct. A congenital weakening of the thoracic duct wall is postulated to be responsible for some thoracic duct cysts.[69] These cysts are exceedingly rare; fewer than 40 cases have been reported in the literature. Histologically, they are similar to the thoracic duct, with the presence of occasional

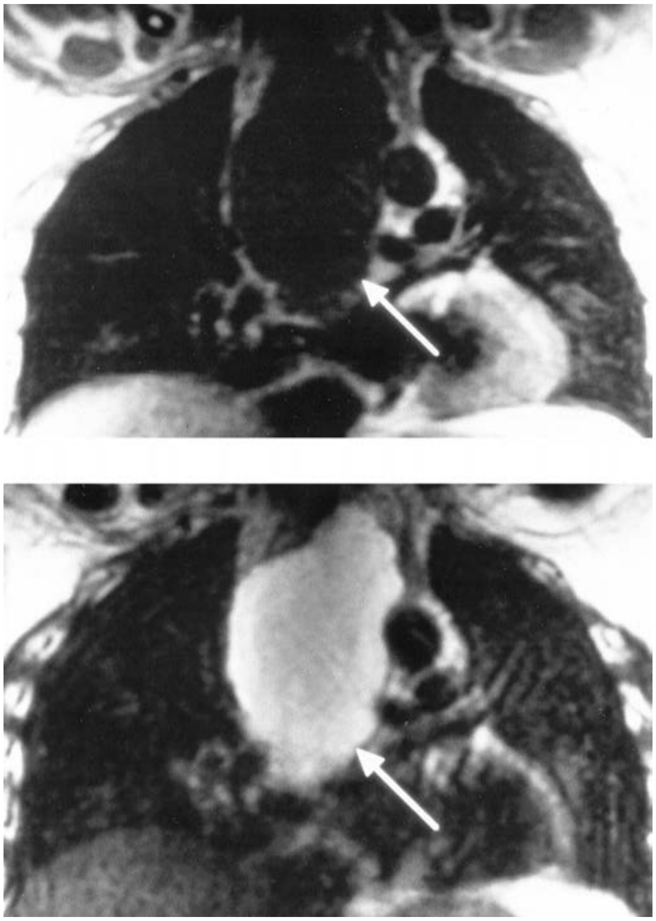

Figure 81-9 MRI scan. Top: Coronal T1-weighted imaging showing a low-intensity mass with a well-circumscribed margin *(arrow)*. Bottom: Coronal T2-weighted imaging showed a high-intensity mass *(arrow)*. *(Reproduced with permission from Chen F, Bando T, Hanaoka N, et al. Mediastinal thoracic duct cyst. Chest. 1999;115(2):584–585.)*

endothelial cells lining the cyst. They occur anywhere along the course of the duct from the cisterna chyli to the supraclavicular area.[70–72] Age at detection varies widely, and up to half of all patients are asymptomatic. Symptoms arise from compression of adjacent structures resulting in dyspnea, cough, chest pain, dysphonia, or dysphagia.[72–74] Plain films may demonstrate a visceral or sometimes paravertebral mediastinal lesion, with CT demonstrating a smooth, homogeneous cystic mass (Fig. 81-8).[15] MRI is superior to CT for evaluation, permitting superior delineation of the cyst boundaries (Fig. 81-9). As thoracic duct cysts can contain varying degrees of lipids and proteins, their MRI characteristics may vary accordingly. Contiguity with the thoracic duct and dilation of the thoracic duct aid the radiologist in making the correct diagnosis.[75] Confirmatory diagnosis may be made using lymphangiography or the presence of high triglyceride content in aspirated fluid, but these techniques are not commonly employed. Endobronchial ultrasound with transbronchial needle aspiration also can lead to the correct diagnosis.[76] Small cysts are generally observed, whereas symptomatic and larger cysts should be resected. Successful surgical management is contingent upon appropriate control of both afferent and efferent thoracic duct pedicles to avoid postoperative chylothorax. Excision can be accomplished through thoracotomy or VATS with application of clips or energy devices that fuse the vessel walls to control the afferent and efferent lymphatic channels.[70,76,77]

CHAPTER 82

Primary Benign and Malignant Neoplasms of the Mediastinum

Natalie S. Lui
Joseph B. Shrager

INTRODUCTION

Primary lesions of the mediastinum are less common than lesions that secondarily involve the mediastinum. Overall, the majority of masses discovered in the mediastinum will be found to be metastases from a primary lung cancer. Neoplasms that arise primarily in the mediastinum, however, are often encountered in the clinic and are represented by a variety of lesions. This chapter first reviews the anatomy of the mediastinum and then focuses on the benign and malignant neoplasms that arise within each of the anatomic regions of the mediastinum. Covered elsewhere in this textbook are nonneoplastic disorders of the mediastinum that include pneumomediastinum, acute mediastinitis, chronic mediastinitis, and other miscellaneous disorders (Chapter 80); as well as congenital lesions of the mediastinum—which are nearly always benign—such as bronchogenic, enterogenous, neurogenic, thymic, pericardial, and thoracic duct cysts (Chapter 81).

ANATOMY OF THE MEDIASTINUM

The mediastinum constitutes an anatomic space located between the thoracic inlet superiorly, the diaphragm inferiorly, and the pleural cavities on the left and right sides. This central anatomic location houses or borders vital structures of almost every major organ system, including the heart and great vessels of the circulatory system, the esophagus of the digestive system, major airways of the respiratory system, the thymus of the immune system, and the phrenic and vagus nerves of the neurologic system. Further, various endocrine organs may extend into it, distant malignancies may metastasize to it, and infectious processes can manifest themselves within it.

The mediastinum is compartmentalized based upon the borders of anatomic structures as seen on a lateral chest radiograph (Fig. 82-1). We believe that the most anatomically appropriate and clinically useful model of the mediastinum is the three-compartment model, which divides the mediastinum into anterior, middle, and posterior compartments.[1] A new classification scheme developed by the International Thymic Malignancy Interest Group divides the mediastinum into similar compartments (prevascular, visceral, and paravertebral) based on computed tomography (CT) scans.[2] The anterior mediastinum extends from the thoracic inlet superiorly to the diaphragm inferiorly, and from the posterior table of the sternum anteriorly to the anterior pericardium and the great vessels posteriorly. It contains most importantly the thymus, but also fat, lymphatic tissues, and the internal mammary arteries and veins. The middle mediastinum is bounded anteriorly by the pericardium and posteriorly by the pericardium and posterior wall of the trachea, extending only as high as the pericardial reflection. It contains the heart, pericardium, superior and inferior vena cavae, ascending and transverse aorta, trachea and mainstem bronchi, and lymphatic tissues. The posterior mediastinum extends from the thoracic inlet to the diaphragm and lies posterior to the posterior pericardium and airway. It contains the descending aorta, thoracic duct, esophagus, vagus nerves, and lymph nodes, as well as structures emerging from the spinal canal such as intercostal nerves.

One of the main advantages of dividing the mediastinum into compartments is the ability to generate a differential diagnosis for a mediastinal mass based on the structures that are contained within the compartment in which it arises (Table 82-1). Such a classification scheme allows a clinician to proceed systematically to determine the appropriate diagnostic or therapeutic approach depending on the differential diagnosis.

EPIDEMIOLOGY AND INCIDENCE

The incidence and type of primary mediastinal neoplasms vary with patient age. In a combined series of 3017 adult patients, thymomas and thymic cysts (26.5%) and neurogenic tumors (20.2%) were the most common, followed by germ cell tumors (GCTs) (13.8%), lymphomas (12.7%), foregut cysts (10.3%), and pleuropericardial cysts (6.6%). In a combined series of 718 children, neurogenic tumors were most common (41.6%), followed by GCTs (13.5%), foregut cysts (13.4%), lymphomas (13.4%), angiomas and lymphangiomas (6.1%), and thymic tumors or cysts (4.9%).[3] In general, the incidence of anterior mediastinal masses is higher in adults, while posterior mediastinal masses predominate in children. Further, the incidence of malignancy differs among primary mediastinal masses arising in each of the different compartments. In one of the largest series, Davis et al. demonstrated that among 400 consecutive patients with mediastinal masses, malignancy was found in 59% of those in the anterior mediastinum, 29% of those in the middle mediastinum, and 16% of those in the posterior mediastinum.[4]

As discussed below, mediastinal masses are often incidentally detected on imaging studies obtained for other reasons. An estimate of the frequency of “incidental” mediastinal masses has been provided by a large lung cancer screening study. Of the 9263 individuals at high risk for lung cancer who underwent CT screening, 71 (0.77%) had a mediastinal mass. The majority of these incidental masses were thymic, and most were managed nonoperatively.[5]

SIGNS AND SYMPTOMS

Signs and symptoms of mediastinal tumors can vary widely at presentation and usually offer only nonspecific clues to the nature of the underlying disease process. While more than 60% of patients do present with symptoms, it is also quite common for an asymptomatic mass to be detected incidentally. Most asymptomatic patients with a mediastinal mass have benign lesions, while most symptomatic patients have an underlying malignant process. In Davis' series of 400 patients with mediastinal masses, only 17% of the lesions found on routine chest radiographs were malignant, but this increased to 57% in symptomatic patients.[4]

The presenting symptoms of a mediastinal mass are influenced by the anatomic location and the presence of malignant invasion or mass effect. Dyspnea or cough may result from airway invasion or abutment, tamponade, or the presence of a pleural effusion. Dysphagia is seen with esophageal compression, and chest pain may represent chest wall or neural invasion or abutment. Invasion of the airway may result in hemoptysis, invasion of the recurrent laryngeal nerve may present as hoarseness, and invasion of the superior vena cava can present with swelling of the face or neck due to superior vena cava syndrome. Constitutional symptoms such as fevers, night sweats, and weight loss (B symptoms) are often associated with

mediastinal lymphoma, and myasthenic symptoms are suggestive of thymoma.

ANTERIOR MEDIASTINAL NEOPLASMS

Below we discuss the clinical evaluation of the patient with an anterior mediastinal mass before individually considering a variety of etiologies.

■ Evaluation of the Anterior Mediastinal Mass

In a patient with an anterior mediastinal mass, it is often possible to make a strong provisional diagnosis based upon clinical evaluation and imaging data.[6] Whereas specific workup for common anterior mediastinal mass lesions is described in the following sections, some general principles are reviewed here.

■ History and Examination

In an individual younger than 40 years, lymphoma is the most likely diagnosis, and the presence of B symptoms (fever, weight loss, or night sweats) or lymphadenopathy elsewhere further increases the level of suspicion. In contrast to lymphoma, thymic neoplasms are very uncommon before the fourth decade of life. The presence of a paraneoplastic syndrome associated with an anterior mediastinal mass (most commonly myasthenia gravis [MG]) essentially clinches the diagnosis of thymoma. The majority of GCTs (benign or malignant) are diagnosed in the second or third decade of life. Whereas patients with a thymoma often have an indolent presentation, patients with a lymphoma or a malignant GCT often have a rapid onset of symptoms. Workup must include examination of the testes to rule out a testicular primary GCT.

■ Serum Studies

Antibodies to the acetylcholine receptor (AChR-Ab) should be measured, as their presence is virtually diagnostic of MG, even if the patient is without obvious symptoms. Tumor markers, such as beta-human chorionic gonadotropin (β-hCG) and alpha-fetoprotein (AFP), are

TABLE 82-1 Structures and Primary Neoplasms in the Three-compartment Model of the Mediastinum

Structures	Common Lesions	Rare Lesions
Anterior compartment		
Thymus	Thymomas	Thymic carcinoma; benign thymic tumors and cysts
Fat and lymphatics	Lymphomas	Vascular lesions
Internal mammary vessels	Germ cell tumors	Mesenchymal tumors
Thyroid (occasional)		Endocrine tumors (e.g., ectopic parathyroid, goiter)
		Castleman disease
Middle compartment		
Heart	Foregut cysts	Pleural and pericardial cysts
Pericardium	Lymphoma	Castleman disease

Sympathetic chain		
Lymph nodes		

elaborated by most malignant GCTs but not by benign GCTs.[7] Elevated serum LDH is suggestive of lymphoma. Evidence of hypo- or hyperthyroidism, as measured by thyroid-stimulating hormone (TSH) and thyroid hormones (T3 and T4), suggests mediastinal goiter, although goiter is not invariably associated with abnormal hormone production.

■ Imaging Studies

CT provides valuable data about the tumor's anatomic location, physical characteristics (fatty, solid, or cystic), and degree of invasiveness. Occasionally, magnetic resonance imaging (MRI) can distinguish cystic from solid masses when unclear on CT[8] or provide useful additional information concerning obliteration of normal tissue planes and vascular invasion. Cysts containing highly proteinaceous fluid can be difficult to separate from solid masses on CT alone. Although imaging is most often not diagnostic of the specific type of tumor, some imaging features can be pathognomonic. For example, the finding of a well-encapsulated lesion in the anterior mediastinum containing several tissue elements—calcium, fat, and fluid—is essentially diagnostic of a mature teratoma.

■ Need for Biopsy

The decision whether to perform a biopsy of an anterior mediastinal mass is not simple. Routine biopsy should not be endorsed, not only because of the unnecessary morbidity and costs associated with the procedure, but also because of the potential risk of tumor spread, particularly for thymoma. If a clinical diagnosis of thymoma is made with a high level of confidence, and the tumor is resectable, surgical resection should be performed without preliminary biopsy, as these tumors have a predilection for local recurrence once the thymic capsule has been violated. Unfortunately, however, this approach may lead to occasional unnecessary resection of lymphoma, which is ideally treated nonsurgically.

Locally invasive or unresectable anterior mediastinal masses should most often be biopsied; such lesions may represent lymphoma, aggressive thymomas that could benefit from neoadjuvant treatment, malignant GCTs that also should be treated initially with systemic therapy, or other rare diseases. These patients should undergo either a CT-guided core needle biopsy or a Chamberlain procedure (anterior mediastinotomy) for diagnosis, depending upon the pathologist's level of comfort in classifying lymphoma on the basis of cytology alone at one's institution. When palpable peripheral nodes are present, the diagnosis of lymphoma is often most easily obtained by excisional biopsy of one of these. Resection of lymphoma is not indicated and can almost always be avoided by performing a diagnostic biopsy when lymphoma is suspected.

Surgical resection is the mainstay of treatment for mature (low-grade) GCTs, and biopsy is not indicated for these lesions if they have the characteristic imaging characteristics. Malignant GCTs, on the other hand, are treated primarily with chemotherapy, radiotherapy, or both; surgery is sometimes considered after a good response to these modalities. In situations where GCT is suspected but tumor markers (AFP and β-hCG) are not markedly elevated, biopsy should be performed.

■ Thymoma

Below are considered the clinical presentation, diagnostic approach, staging, treatment, and outcomes for patients with thymoma.

Presentation

The age distribution of patients with a thymoma is represented by a broad peak between approximately 35 and 70 years with a median age of about 54 years.[9] The ratio of men to women with this disease is about equal. Approximately one-third of patients with a thymoma will not report significant symptoms, and one-third will report symptoms of cough, dyspnea, or chest pain reflective of compression or invasion of adjacent structures. Patients may also present with symptoms of an associated paraneoplastic syndrome. Some 40% to 45% of patients with a thymoma will present with MG, and, conversely, 5% to 15% of patients with MG will be found to have a thymoma.[10–12] Thymomas may also be associated with pure red cell aplasia, agammaglobulinemia, systemic lupus erythematosus, and other autoimmune disorders; these respond less consistently than MG to thymectomy.[13]

Diagnosis

A clinical diagnosis of thymoma is often sufficient to proceed to resection without biopsy (see above). The presence of a paraneoplastic syndrome associated with an anterior mediastinal mass essentially clinches the diagnosis of thymoma. Antibodies to the acetylcholine receptor (AChR-Ab) should be measured, and their presence is diagnostic of MG and also clinches the diagnosis of thymoma. Interestingly, AChR-Ab are demonstrated in approximately 60% of patients who have thymoma without neurologic symptoms.[14] In addition, MG can develop some time after diagnosis of thymoma, and occasionally even following resection, highlighting the necessity of complete resection of both the thymoma and the entire thymus gland. All patients with thymoma should have preoperative

AChR-Ab testing, even if asymptomatic, since positive levels are a risk factor for development of MG after thymectomy.[15–17]

It is not necessary to obtain a preoperative tissue biopsy for a small, resectable anterior mediastinal tumor whose radiographic features are typical of thymoma in an asymptomatic patient. Although there are no pathognomonic imaging features that differentiate thymoma from several other mediastinal tumors, in a patient without B symptoms to suggest lymphoma, the diagnosis of thymoma is strongly suggested by a CT scan demonstrating a well-circumscribed, solid anterior mediastinal mass without the low-density areas that would suggest the cystic and fatty components of a teratoma (Fig. 82-2). Most thymomas are solid tumors, but up to a third may have components that are necrotic, hemorrhagic, or cystic. Several small studies have investigated the utility of PET in evaluation of thymoma and have suggested greater FDG uptake in thymic carcinoma and lymphoma compared with thymoma.[18–20] Our institutional experience with 77 patients with an anterior mediastinal mass eventually shown to be either thymoma or lymphoma showed that 100% of discrete mediastinal tumors were thymoma and thus could be safely resected without the need for preliminary biopsy, while 100% of tumors with SUVmax above 12.85 were lymphoma.[21]

Once a diagnosis of thymoma is strongly supported, the goal is to proceed directly to resection without preliminary biopsy, as these tumors have a predilection for local recurrence once the capsule has been violated. A definitive tissue diagnosis is needed primarily when a presumed thymoma is so advanced that it would be best treated either nonoperatively or with neoadjuvant chemotherapy or chemoradiotherapy, or in instances where there is a strong possibility of lymphoma. If required, the pathologic diagnosis of thymoma can usually be achieved by image-guided core needle biopsy, or if that fails, through open surgical biopsy. The success rate of needle biopsy in establishing the diagnosis of thymoma is approximately 60%, and the success rate of surgical biopsy is approximately 90%.[22]

In our opinion, video-assisted thoracoscopic surgical (VATS) biopsy of an anterior mediastinal mass in which thymoma is in the differential should be assiduously avoided, due to the great potential of spread into the pleural space. If core needle biopsy fails and a diagnosis is required, a Chamberlain procedure (anterior mediastinotomy) is typically the better approach than VATS.

All patients with suspected thymoma should be evaluated for MG. This evaluation usually begins with a careful assessment for the presence of ocular, bulbar, and limb muscle weakness. The diagnosis of MG in a patient with a characteristic history and physical examination requires two positive confirmatory tests among pharmacologic (Tensilon test), serologic (AChR-Ab), and electrodiagnostic (EMG) studies. If there is any suggestion of MG on initial presentation, the patient should undergo preoperative evaluation by a neurologist. Medical optimization prior to surgery using some combination of cholinesterase inhibitors, intravenous immunoglobulin, plasmapheresis, and occasionally steroids, can help avoid the rare occurrence of respiratory failure or a myasthenic crisis in the perioperative period.

Staging

The most widely utilized classification scheme for thymoma was proposed by Masaoka in 1981 and is based on the local invasiveness of the tumor (Table 82-2).[23] The Masaoka classification system has prognostic value and permits stratification for adjuvant therapy.[24] One difficulty with this system is that it is based upon the findings at the time of surgical resection, thus precluding its use for triaging some patients to neoadjuvant therapy. The American Joint Committee on Cancer adopted a Tumor, Node, Metastasis (TNM) staging system in the eighth edition (Table 82-3) that was created by an international collaboration that included the International Thymic Malignancy Interest Group (ITMIG) and the International Association for the Study of Lung Cancer (IASLC).[25,26] This system frequently stages tumors lower (for example, macroscopic invasion into the mediastinal pleura is stage I in the TNM system) and will reduce recommendations for adjuvant radiation therapy.[27] In addition, it is unclear whether mediastinal lymph node staging is necessary when only 2% of thymomas have involved nodes, and these nodes are difficult to access through minimally invasive techniques.[27]

Thymomas are also classified histologically. A thymoma is composed of a mixture of thymic epithelial cells with bland features as well as lymphocytes in various stages of development. The neoplastic cell of origin is believed to be the thymic epithelial cell and not the lymphocyte,[28] and thymomas appear histologically benign even when they are invasive. In 1985, Müller-Hermelink proposed a novel histologic classification system to separate all thymomas into categories of cortical, medullary, or mixed, based on the histologic appearance of the thymic epithelial cells.[29] Cortical thymomas are composed of large, round, or polygonal epithelial cells, and medullary thymomas contain smaller, spindle cell–shaped epithelial cells with irregular nuclei. This histologic classification system was found

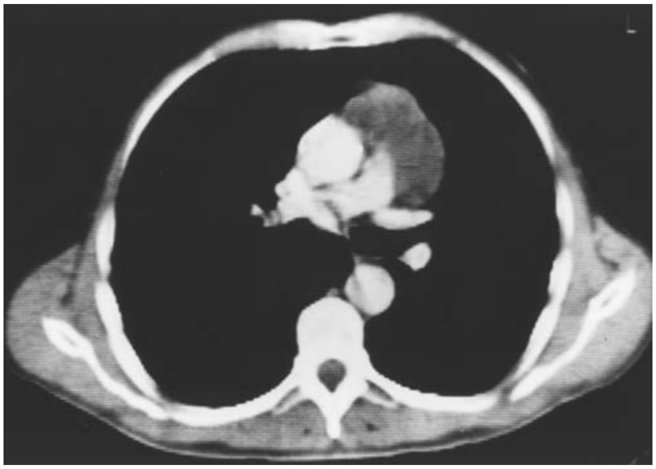

Figure 82-2 Thymoma. Axial section from a CT scan demonstrates a 4-cm mass abutting the thoracic aorta without any evidence of invasion.

TABLE 82-2 Masaoka Staging of Thymic Malignancies

Stage	Description	10-Year Survival (%)
I	Encapsulated tumors without gross or microscopic invasion	90 (75–100)
II	Transcapsular invasion	75 (42–100)
IIA	Microscopic invasion	
IIB	Macroscopic invasion	
III	Macroscopic invasion of surrounding tissues (lung, pericardium, vena cava, or aorta)	56 (26–84)
IVA	Disseminated disease within the chest	38 (22–47)
IVB	Distant metastases	Unknown

to reliably predict tumor behavior and prognosis, with medullary thymomas behaving in an essentially benign fashion and cortical thymomas more frequently demonstrating evidence of invasive and malignant disease.[30] Later studies have demonstrated that both the Masaoka staging and Müller-Hermelink grading systems are strong and independent prognostic indicators of both overall and disease-free survival.[24,31,32]

More recently, the World Health Organization (WHO) proposed a histologic classification system (resembling the Müller-Hermelink system) that has become the histologic grading system of choice in the current era and is useful to distinguish between thymoma, thymic carcinoma, and thymic carcinoids (Table 82-4).[33] It is now accepted that the Masaoka or TNM staging criteria used in combination with the WHO grading criteria provides the most accurate prognostic information for survival and recurrence in thymoma.[34,35]

Treatment

Surgical resection is the mainstay of treatment for Masaoka stage I–III thymoma while the treatment of stage IVa thymoma is controversial. Resection of even a small stage I thymoma with MG should include removal of the entire thymus, as total thymectomy is the ideal treatment for MG even in the absence of thymoma. Total thymectomy should also be performed in all cases where AChR-Abs are present in asymptomatic patients. Asymptomatic patients with no antibodies and small tumors may do equally well with a thymomectomy without total thymectomy, as long as wide tumor-free margins can be achieved. The gold standard surgical approach to thymoma remains median sternotomy, but minimally invasive approaches including VATS and robotic techniques are likely equally effective for smaller tumors in experienced hands.[36,37] It is critically important, however, that the tumor capsule not be disrupted during surgery to avoid pleural dissemination, and thus a "no-touch" technique is always used whether via median sternotomy or minimally invasive approaches. Certainly, if there is suspicion of invasion into adjacent structures, sternotomy is the preferred approach as it is critical that the involved portions of these structures are resected en bloc with the thymus gland and tumor. This may require resection of lung, pericardium, innominate vein, superior vena cava, phrenic nerve, and even aorta.

Stage I thymomas are treated adequately with complete resection alone. Thymoma is a radiosensitive tumor, and postoperative radiotherapy is recommended for patients who have incomplete resection. It is sometimes used after complete resection for stage II and higher thymoma, although there are conflicting data about additional benefit.[38–40] For patients with stage III or IV thymoma, chemotherapy is recommended and is often administered preoperatively, followed by radiation for patients with incompletely resected disease. For thymoma that is initially considered unresectable, induction chemotherapy followed by surgical resection can result in favorable rates of overall and disease-free survival.[41,42] Further, surgical resection plays an important role in the management of recurrences, and complete resection of a recurrence may result in improved overall survival.[43] Immunotherapy is rarely used

TABLE 82-4 World Health Organization (WHO) Histologic Classification System of Thymomas

Type	Description
A	Tumor in which foci having features of type A thymoma are admixed with foci rich in lymphocytes
B1	Tumor resembles normal functional thymus; combines large expanses having an appearance practically indistinguishable from that of normal thymic cortex with areas resembling thymic medulla
B2	Tumor in which neoplastic epithelial component appears as scattered plump cells with vesicular nuclei and distinct nucleoli among a heavy population of lymphocytes; perivascular spaces are common and sometimes very prominent; a perivascular arrangement of tumor cells resulting in a palisading effect may be seen
B3	Thymoma predominantly composed of epithelial cells having a round or polygonal shape and exhibiting no or mild atypia; they are admixed with a mild component of lymphocytes, resulting in a sheet-like growth of the neoplastic epithelial cells
C	Thymic tumor exhibiting clear-cut cytologic atypia and a set of cytoarchitectural features no longer specific to the thymus, but rather analogous to those seen in carcinomas of the other organs; type C thymomas lack immature lymphocytes; whatever lymphocytes may be present are mature and usually admixed with plasma cells

for thymoma given the increased risk of immune-related adverse events.[44]

Outcome

Although thymomas (not thymic carcinomas) are generally indolent tumors, they should be considered a malignant neoplasm as they have the ability to metastasize locoregionally to the pleura, pericardium, and, rarely, to distant sites. One study reported that 4% of 207 patients evaluated for surgical resection of a thymoma had lymph node or distant metastasis at presentation, and another 16% developed nodal or distant metastases at some point in their course.[45] Other studies have shown that distant metastases can occur with any stage or histology.[46,47]

Detterbeck reviewed 15 surgical series of at least 100 patients each (2437 patients total) and demonstrated favorable 10-year survival rates of approximately 90% for stage I, 70% for stage II, 55% for stage III, and 35% for stage IVa thymoma.[22] Complete resection is the most important prognostic factor and is associated with longer survival in all large studies examining this issue.

Locoregional recurrence is far more common than distant recurrence, and about half of all local recurrences involve the pleural space or the lung. The average recurrence rate for stage I tumors is 3% but increases to 11% and 30% for stage II and III tumors, respectively.[9] The relatively indolent nature of a thymoma is reflected by an average time to recurrence of 5 years, with rare recurrences seen as far out as 20 years.

The presence of MG is no longer considered a negative prognostic factor, as it was in older studies. More than 30% of patients with MG and thymoma ultimately achieve a complete remission of the MG following thymectomy, and up to 80% have some degree of improvement in their MG.[48] Of note, a randomized trial recently showed improved MG outcomes after extended thymectomy in most patients with MG without thymoma.[49] Similarly, approximately one-third of patients with associated red cell aplasia experience improvement following thymectomy. In contrast, hypogammaglobulinemia associated with thymoma generally does not respond to thymectomy.

■ Thymic Carcinoma

A clinical approach to diagnosis and management of thymic carcinoma is considered in the sections that follow.

Presentation

Thymic carcinomas (WHO type C malignant thymic epithelial tumors) are highly aggressive neoplasms of thymic epithelial origin and are very different from thymomas (WHO types A, AB, and B). Thymic carcinomas are rare, constituting approximately 10% of all thymic neoplasms.[43] They can occur at any age but are most frequently observed in persons between 30 and 60 years of age. Most patients with thymic carcinoma present with symptoms of local invasion or compression such as cough, chest pain, or superior vena cava syndrome. Pericardial and/or pleural effusions are often seen. Thymic carcinoma is typically not associated with MG. Unlike thymomas, thymic carcinomas frequently metastasize to lymph nodes and distant sites. Eighty percent of patients have local invasion of contiguous mediastinal structures at the time of presentation, and 40% of cases have metastatic spread to bones, lung, pleura, liver, or lymph nodes.[50] More than half of the patients will present with locally advanced, although potentially resectable, disease.[51,52]

Diagnosis

Thymic carcinomas can be distinguished from thymomas based on their malignant histologic features and different immunohistochemical and genetic characteristics. Imaging studies often reveal a more invasive presentation, and for this reason, and because lymphoma and thymic carcinoma can appear similar on imaging, percutaneous needle biopsy should generally be undertaken in patients with clear invasion of surrounding structures on imaging.

Staging

The Masaoka and TNM staging systems and the WHO histologic classification system are used to stage thymic carcinoma, just as in thymoma. In the WHO system, thymic carcinomas are type C lesions. These tumors are distinct from thymoma and should not be considered in the same light as a thymoma with local invasion. Histologically, thymic carcinoma contains a number of different cell types, but they are unified by their unequivocal malignant appearance on light microscopy. Division of patients into those with low-grade histology and those with high-grade histology has prognostic significance. The median survival for patients with low-grade histology (squamous, mucoepidermoid, and basaloid thymic carcinomas) is 29 months, compared with 11 months for patients with high-grade histology (sarcomatoid and clear cell thymic carcinoma).[53]

Treatment

While there is no standard-of-care approach to patients with thymic carcinoma, a multidisciplinary strategy is recommended. The prevailing practice is that patients with stage I–III and some IVa patients believed to have resectable disease should be treated with some combination of surgical resection plus chemotherapy and/or radiotherapy.[54] For the rare thymic carcinoma patients with clearly resectable disease, surgery is considered the primary therapeutic modality. For those with disease thought to be initially unresectable or disease that appears likely to be invading one or more surrounding organs or major vascular structures, neoadjuvant chemotherapy and/or radiation may improve operability and permit subsequent resection.[53,55,56] Immunotherapy has been used for refractory or recurrent thymic carcinoma, but there is concern for immune-related adverse events.[44]

Outcome

The prognosis for patients with thymic carcinoma is much worse than for patients with thymoma, with 5-year overall survival rates in the range of 30% to 50%.[52,57,58] A more recent clinicopathologic study of 65 cases of primary thymic carcinoma, however, reported a more favorable 5-year survival rate of 66%. In this study, 63% of the patients received additional therapy in the form of chemotherapy or radiation.[51] Similar to thymoma, patients with completely resected thymic carcinomas have longer overall and progression-free survival rates than those who undergo incomplete resection or are unresectable. In a recent series of 60 patients with thymic carcinoma (40 treated surgically), complete resection and early Masaoka stages are the most important factors associated with successful disease control and long-term survival. Five-year survival of 85% was obtained after complete resection, compared with 29% in those with incomplete resection.[59] In another series of 16 patients, a multimodality approach that included surgery resulted in complete resection in 88% of the patients and a mean survival of 4.2 years for the entire group.[60]

■ Other Thymic Neoplasms

Clinical assessment and management of a variety of other thymic neoplasms are considered below.

Thymic Hyperplasia

Thymic hyperplasia is a term used to describe either a histologically normal thymus that is enlarged for the patient's age, or a thymus that histologically shows cellular hyperplasia, which is also generally associated with gross enlargement of the gland. This condition can present as a spectrum of disease ranging from respiratory compromise due to impingement on the airway (almost exclusively in the pediatric population) to the more common situation of an incidental finding on an unrelated imaging study. Many of the thymus glands removed from patients with MG demonstrate "true thymic hyperplasia" (cellular hyperplasia), and this is thought to contribute to the pathogenesis of the disease. In addition to MG, thymic hyperplasia can be seen following severe or chronic illness, the so-called "thymic rebound." Steroid use will also generally lead to substantial thymic hyperplasia. Practically speaking, when a diffusely enlarged thymus without a discrete mass is discovered in an otherwise asymptomatic patient without elevated serum AChR-Abs, this can be followed expectantly, as these glands have a negligible risk of harboring significant thymic disease.[61]

Thymolipoma

Thymolipomas are distinguished from simple mediastinal lipomas by their location within the thymic capsule. Histologically, these neoplasms are composed of mature adipocytes as well as normal thymic components.[62] Thymolipomas, like thymomas, can be associated with thymic paraneoplastic syndromes such as red cell aplasia, hypogammaglobulinemia, and aplastic anemia. These lesions can grow to significant size and result in compressive and obstructive symptoms. The treatment of thymolipomas is surgical excision.

Thymic Neuroendocrine Tumors

Thymic neuroendocrine tumors, also known as thymic carcinoid tumors, are very rare neoplasms of the thymus.[63] They have a strong association with endocrinopathies such as multiple endocrine neoplasia type I. Unlike other carcinoids, they rarely present with carcinoid syndrome, but many do secrete adrenocorticotropic hormone (ACTH) resulting in Cushing syndrome. Thymic neuroendocrine tumors tend to be very aggressive. Upon presentation, most thymic carcinoids are locally invasive and almost half of all patients will have metastatic disease.[64,65] Surgery is the therapy of choice for resectable thymic neuroendocrine tumors and should include aggressive wide margins. The prognosis is poor despite aggressive therapy, and most patients present with local recurrence or metastases within 5 years of surgery and will die within 10 years.

Germ Cell Tumors

Germ cell tumors (GCTs) constitute a group of neoplasms that arise from gonadal tissue. The anterior mediastinum is the most common location for occurrence of extragonadal GCTs. GCTs account for 15% of all anterior mediastinal masses in adults (85% of which are benign, mature GCTs) and 25% of anterior mediastinal masses in children.[66] GCTs typically occur in young adults in the second to fourth decades of life with no gender predilection.

While previously thought to be metastatic from a gonadal primary, it is now accepted that these neoplasms are primary mediastinal tumors. The precise origin of the germ cells that form these tumors in sites heterotopic to the gonads is still not completely clear, but it is postulated that mediastinal GCTs may result from aberrant migration of germ cells during embryonic development. Because primordial germ cells are undifferentiated cells from which a variety of different tumors can arise, there have been numerous overlapping and sometimes confusing classification and grading systems proposed for these tumors. Even more confusing for classifying GCTs is that it is common to see two or more GCT histologies arising from within a single mass. Based on the need for standard classification, investigators from the Armed Forces Institute of Pathology developed a reproducible histologic classification system (Table 82-5) and clinical staging system (Table 82-6) based on review of more than 300 cases.[67]

TABLE 82-5 Classification of Mediastinal Germ Cell Tumors

Mature teratoma
Immature teratoma
Teratomas with malignant component:
Type I: with an associated GCT (seminoma, etc.)
Type II: with another epithelial malignancy (squamous, adenocarcinoma, etc.)
Type III: with sarcomatous component (rhabdomyosarcoma, osteosarcoma, etc.)
Type IV: a combination of any of the above
Seminoma
Yolk sac tumor (endodermal sinus tumor)
Embryonal carcinoma
Choriocarcinoma
Combined GCT without teratomatous component

Mediastinal GCTs include benign and malignant neoplasms that for descriptive purposes can be simplified into three categories. Benign tumors are primarily benign mediastinal teratomas, which account for 60% of all mediastinal GCTs. Malignant tumors are divided into seminomatous GCTs, which account for 40% of malignant mediastinal GCTs, and nonseminomatous GCTs (NSGCTs) which account for 60% of malignant mediastinal GCTs. NSGCTs include embryonal cell carcinomas, choriocarcinomas, yolk sac tumors, and malignant teratomas.

Mediastinal Teratomas

Teratomas are defined by the presence of tissue from more than one of the three primitive germ cell layers. Mature (benign) teratomas are composed of well-differentiated elements such as fat, muscle, and cartilage (mesoderm); hair, skin, and teeth (ectoderm); and intestinal tissue (endoderm). Mature teratomas can be symptomatic or asymptomatic upon presentation. Symptoms may include chest pain, dyspnea, cough, or fever (if the tumor becomes infected). Occasionally the tumor may erode into an airway and a patient may cough up hair (trichophytosis) or oily sebum that is pathognomonic of a benign mediastinal teratoma.

CT with contrast is the diagnostic procedure of choice and usually demonstrates a thick-walled cystic mass. Calcification is often present, and when this is intermixed with areas of fat and/or fluid

TABLE 82-6 Clinical Staging of Mediastinal Germ Cell Tumors

Stage	Characteristics
I	Well-circumscribed tumor with or without focal adhesions to the pleura or pericardium but without microscopic evidence of invasion into adjacent structures
II	Tumor confined to the mediastinum with macroscopic and/or microscopic evidence of infiltration into adjacent structures (pleura, pericardium, great vessels)
III	Tumor with metastases
IIIA	With metastases to intrathoracic organs (lymph nodes, lung, etc.)
IIIB	With extrathoracic metastases

density, the diagnosis can be made radiographically with a high degree of certainty.[68] Benign teratomas can also be primarily solid, and in these cases the diagnosis is more challenging. Tumor markers such as β-hCG and AFP should be measured but will not be elevated in benign teratoma. Needle biopsy of a mass that is highly suspected to be a benign teratoma based on imaging is not necessary. Such a patient should go directly to surgical resection.

The treatment for benign GCTs is total resection before the development of complications. Even benign teratomas are frequently densely adherent to adjacent structures such as lung, blood vessels, and pericardium; en bloc resection of involved structures is sometimes required, although mature surgical judgment must be exercised in determining when a near-complete resection is satisfactory for these benign lesions. Radiation and chemotherapy play no therapeutic role unless concurrent malignant disease is present. Outcome after resection of a benign teratoma is excellent, with 10-year survival exceeding 90%.[69] Occasionally, teratomas will contain less well-differentiated tissues and behave more aggressively, resembling malignant teratomas (see below).

Malignant Seminomatous Germ Cell Tumors

Malignant GCTs, both seminomatous and nonseminomatous, are almost exclusively diseases of men. Seminoma usually presents during the third or fourth decade of life as a large anterior mediastinal mass, although it rarely occurs in the middle and posterior mediastinum. Most patients are symptomatic upon presentation; symptoms are variable and most commonly include chest pain and dyspnea.[70]

Careful bimanual examination and ultrasound of the testicles should be performed to rule out a primary testicular tumor, and a thorough staging workup should be performed including CT scan of the abdomen (looking primarily for retroperitoneal disease) along with the chest. Measurement of serum tumor markers is critical to the diagnosis and follow-up of patients with mediastinal seminomas. Patients with mediastinal seminomas will typically demonstrate mild elevation of β-hCG (<100 mIU/mL), while higher levels than this should raise the suspicion of a mixed tumor or an NSGCT.[71] An elevated AFP level excludes the diagnosis of seminomatous tumor and defines the tumor as an NSGCT or mixed GCT.

Chest CT is the most useful imaging modality for a seminoma, which typically appears as a large, bulky homogeneous mass that may obscure tissue planes or invade adjacent structures and is often surrounded by bulky lymphadenopathy (Fig. 82-3). These tumors are usually FDG-avid, and PET may be useful in monitoring response to therapy. A biopsy is usually necessary to secure the diagnosis and percutaneous core needle biopsy is the preferred initial approach, reserving open surgical biopsies for cases in which percutaneous sampling is inconclusive.

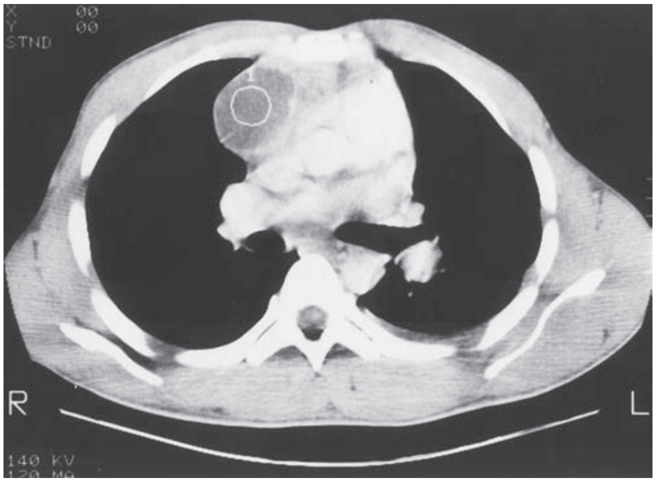

Figure 82-3 Mediastinal seminoma. Axial section from a CT reveals a homogeneous mass within the anterior mediastinum.

Some 60% to 70% of patients with mediastinal seminoma will present with metastatic disease, primarily to intrathoracic organs, although distant metastases also can be found. The treatment of primary mediastinal seminomatous tumors has evolved over the past 20 years from a primarily surgical approach to a chiefly nonsurgical approach. It has become clear that the first line of treatment in all cases of mediastinal seminoma should be chemotherapy, and 5-year survival rates exceeding 90% are achieved with cisplatin-based chemotherapy regimens.[72,73] As is the case with testicular seminomas, pure mediastinal germ cell seminomas are radiosensitive. Whereas radiotherapy alone may achieve complete remission in only about 65% of patients,[74] the addition of radiotherapy to chemotherapy appears to enhance the benefit of chemotherapy alone. The role of surgical resection in this disease remains controversial. Surgery is generally reserved for patients with residual mediastinal masses following chemotherapy and radiation when residual active disease is a concern (e.g., with persistently elevated or rising markers, or increasing FDG avidity on PET). The benefits of surgical resection in this setting would be to document if there is residual malignant seminomatous tumor (as opposed to necrotic debris) and to completely resect it; in addition, occasional patients have a previously unrecognized nonseminomatous malignant component of the tumor.[75]

Malignant Nonseminomatous Germ Cell Tumors

NSGCTs are malignant tumors that are seen almost exclusively in men. There is a particular propensity for men with Klinefelter syndrome to develop these tumors. A variety of nonseminomatous histologies have been categorized, and their incidence is best gathered from a large published series of 229 cases.[67] NSGCTs are composed of teratocarcinoma (41%), endodermal sinus (yolk sac) tumor (35%), choriocarcinoma (7%), embryonal carcinoma (6%), and mixed histologies (11%). Further, non–germ cell components including sarcoma or epithelial carcinoma were found in 58% of teratocarcinomas.

Mediastinal NSGCTs are characterized by rapid local growth and early distant metastases, and patients often present with advanced disease. Most patients will have symptoms caused by compression or invasion of adjacent structures. Constitutional symptoms, including weight loss, fever, and weakness are more common in patients with NSGCT compared with pure seminoma. Like seminoma, sites of metastases in NSGCT include the lung, pleura, lymph nodes, and liver; 85% to 95% of patients with an NSGCT will have at least one site of metastases.[76,77]

Workup should include CT of the chest and abdomen and measurement of serum tumor markers. Chest CT will typically reveal a large, irregular anterior mediastinal mass with poorly defined margins and multiple areas of necrosis and hemorrhage (Fig. 82-4). Unlike seminoma, more than 90% of patients with NSGCT will have an elevation of either β-hCG (30%–35% of patients) or AFP (80% of patients), and an AFP level greater than 500 ng/mL is essentially diagnostic of NSGCT.[71,78] NSGCTs, especially those with yolk sac histology, are associated with a variety of hematologic malignancies including leukemia, and these occur independently of the chemotherapy used to treat the tumor.[79]

As most patients present with bulky or metastatic disease, surgical resection is not the first line of treatment. Historically, patients with NSGCT had an exceedingly poor prognosis, but this has dramatically improved with the implementation of intensive cisplatin-based chemotherapy protocols. A summary of studies of patients treated with first-line cisplatin-based combination chemotherapy

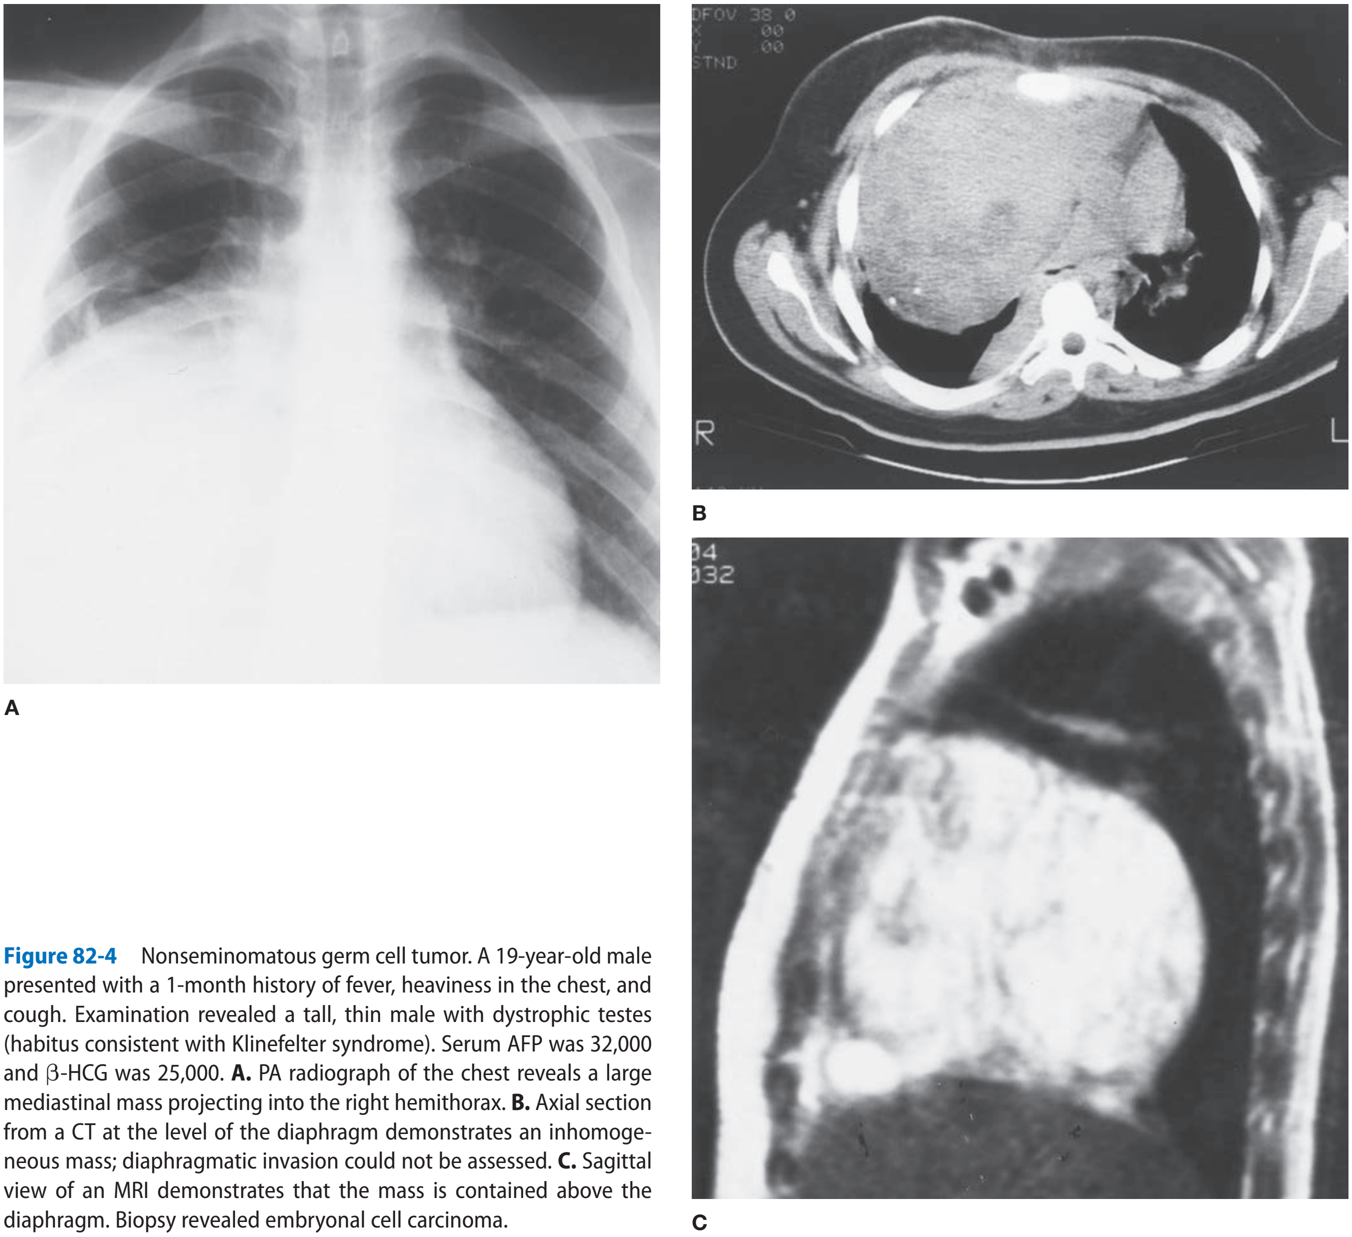

Figure 82-4 Nonseminomatous germ cell tumor. A 19-year-old male presented with a 1-month history of fever, heaviness in the chest, and cough. Examination revealed a tall, thin male with dystrophic testes (habitus consistent with Klinefelter syndrome). Serum AFP was 32,000 and β-HCG was 25,000. **A.** PA radiograph of the chest reveals a large mediastinal mass projecting into the right hemithorax. **B.** Axial section from a CT at the level of the diaphragm demonstrates an inhomogeneous mass; diaphragmatic invasion could not be assessed. **C.** Sagittal view of an MRI demonstrates that the mass is contained above the diaphragm. Biopsy revealed embryonal cell carcinoma.

regimens showed an overall long-term survival rate of 42%.[80] After completion of chemotherapy, patients should be restaged with a CT of the chest and abdomen, and serum tumor markers should be remeasured.

Most patients will be found to have residual masses or radiographic abnormalities after completing chemotherapy. Regardless of whether tumor markers are elevated, these patients should undergo surgical resection of residual masses if technically feasible because salvage chemotherapy is usually ineffective,[81] and surgical resection is curative in a substantial portion of patients.[82,83] In addition, occasional patients will be found to have a previously unrecognized mature (benign) teratoma component, which can be cured only by resection.

■ Lymphoma

Both Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL) can present as anterior mediastinal masses. HL accounts for approximately 50% to 70% of mediastinal lymphomas. The three most common types of lymphoma found in the mediastinum are nodular sclerosing HL, large cell lymphoma, and lymphoblastic lymphoma.[84] In general, these are systemic diseases that also involve the mediastinum, although some patients do present with disease limited to the mediastinum alone. Due to the generally widespread nature of these diseases, treatment is centered on systemic chemotherapy and radiation is the primary modality used for local control. Surgery is not typically utilized as a therapeutic option but may be required to make a histologic diagnosis.

Hodgkin Lymphoma

HL has a bimodal age distribution with its incidence peaking in young adulthood and again after 50 years of age. HL is divided into four subtypes: nodular sclerosing (most common), lymphocyte-rich, mixed cellularity, and lymphocyte-depleted. Most patients present with asymptomatic lymphadenopathy, but up to 25% of patients will experience B symptoms consisting of fever, night sweats, and weight loss.[85] Over half of all patients with HL will have involvement of the mediastinum, almost always in the anterior mediastinum or involving paratracheal lymph nodes (Fig. 82-5). Suspicion for HL warrants a tissue biopsy, and the presence of Reed–Sternberg cells is pathognomonic. Because the tumors tend

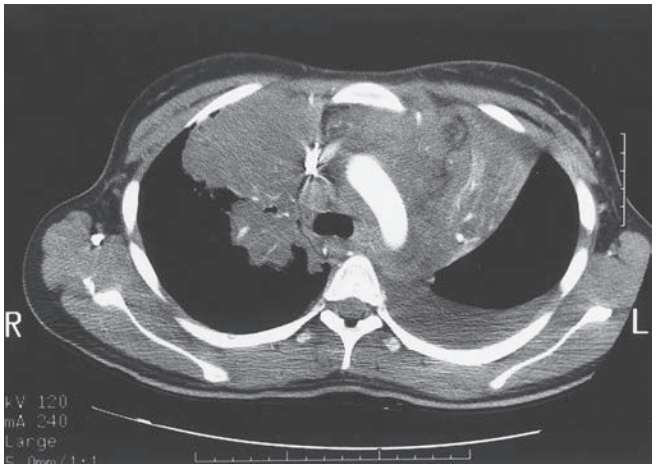

Figure 82-5 Hodgkin disease. Axial section from a CT shows a bulky mediastinal mass and pleural effusion.

to be quite fibrotic, with only scattered malignant cells, surgical biopsy is often required to establish a diagnosis, either by cervical mediastinoscopy (for paratracheal or middle mediastinal nodes) or by anterior mediastinotomy (for anterior mediastinal masses). PET generally demonstrates high FDG avidity in lymphomas, and therefore PET/CT may be useful in guiding sites for biopsy. The Lugano classification (Table 82-7) is used for staging and is based on the Ann Arbor classification with Cotswolds modification. Invasive staging (laparotomy and splenectomy) has fallen out of favor.[86]

Treatment approaches to HL are separated into those for early-stage disease (stage I and II) and advanced-stage disease (stage III and IV). Modern treatment protocols most often involve chemotherapy and radiation therapy. Patients with advanced-stage disease as well as patients with B symptoms are treated with chemotherapy regimens such as ABVD (Adriamycin, bleomycin, vinblastine, dacarbazine). Radiation is sometimes used in cases of bulky disease, and patients who relapse may benefit from a hematopoietic stem cell transplant. Cure rates are greater than 90% for stage I and II HL, 30% to 90% for stage IIIA, 60% to 70% for stage IIIB, and 50% to 60% for stage IV.[84,85]

TABLE 82-7 Lugano Classification of Hodgkin and Non-Hodgkin Lymphoma (Based on the Ann Arbor Staging System with Cotswolds Modification)

Stage	Characteristics
I	Involvement of one lymph node region (one node or a group of adjacent nodes) or single extranodal lesion (I_E)
II	Two or more lymph node regions on the same side of the diaphragm, or limited contiguous extranodal involvement (II_E)
III	Lymph node regions or lymphoid structures on both sides of the diaphragm
IV	Noncontiguous extralymphatic involvement
Modifications	
A	Absence of systemic B symptoms (only for Hodgkin lymphoma)
B	Fever, night sweats, weight loss >10% in 6 months (only for Hodgkin lymphoma)
E	Extranodal involvement
Bulky	Bulky disease (a nodal mass greater than 10 cm or greater than one-third of the transthoracic diameter) is described by the size, no longer with X

Non-Hodgkin Lymphomas

Non-Hodgkin lymphoma (NHL) is a heterogeneous group of systemic diseases that are categorized into many classes and grades. Mediastinal tumor burden in NHL is more likely to be part of the generalized disease process than the main focus of disease, and only 20% of patients with NHL will have involvement of the mediastinum at the time of presentation. This disease is not limited to the anterior mediastinum and can occur in the middle and posterior mediastinal compartments. Of patients with primarily mediastinal disease, the majority will have either lymphoblastic lymphoma or large B-cell lymphoma. The mean age of presentation for these patients is between 28 and 35 years.

Lymphoblastic lymphomas are highly aggressive tumors, and invasive symptoms including cough, wheezing, dyspnea, and manifestations of superior vena cava syndrome, cardiac tamponade, or tracheal obstruction are common. The central nervous system, skin, and gonads may be involved and bone marrow involvement with blasts is relatively common.[84] Primary mediastinal B-cell lymphoma is composed histologically of large cells with expression of the B cell–associated antigen CD20; immunohistochemistry and/or flow cytometry are critical to the diagnosis. Presentation with symptoms related to invasion or obstruction of adjacent structures is common, but there is less involvement of extrathoracic sites and bone marrow than in lymphoblastic lymphoma. Staging of NHL is performed according to the Lugano classification, and CT scans of the chest, abdomen, and pelvis are the initial and often only necessary imaging (Fig. 82-6).

Treatment regimens for mediastinal NHL are dependent upon stage and histologic subtype. Due to its propensity to involve the bone marrow, treatment of lymphoblastic lymphoma commonly employs a regimen similar to that for acute lymphoblastic leukemia, often including intrathecal chemotherapy and bone marrow transplantation. Patients with primary mediastinal B-cell lymphoma can be treated with conventional chemotherapy regimens, but high-dose chemotherapy and "involved field" radiotherapy are sometimes employed. In general, relapses in NHL are common and the long-term prognosis is worse than for HL.

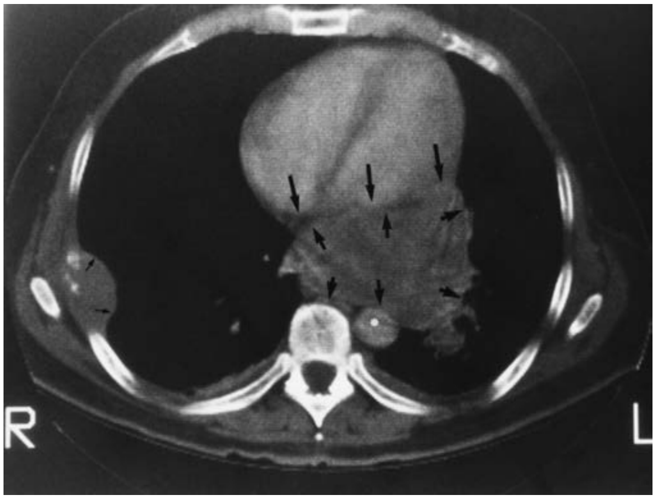

Figure 82-6 Non-Hodgkin lymphoma. Axial section from a CT demonstrates a large middle and posterior mediastinal mass with distant metastasis to a rib in the contralateral chest. This skip involvement is typical of non-Hodgkin lymphoma.

Other Anterior Mediastinal Neoplasms

Other anterior mediastinal neoplasms include substernal thyroid and parathyroid adenoma.

Substernal Thyroid

Substernal and ectopic thyroid tissue can present as an anterior mediastinal mass but may involve the middle mediastinum if the thyroid tissue descends more caudally into the paratracheal space. In most cases, the substernal thyroid is a euthyroid goiter and an enlarged thyroid gland will be palpable in the neck. We have found that a noncontrast CT is the single most useful test in differentiating substernal thyroid from other mediastinal masses. Because of its iodine content, substernal thyroid tissue shows enhancement on a noncontrast CT scan, and this along with a visible connection to the gland within the neck usually confirms the diagnosis. I-123 SPECT/CT can also be useful for characterization of mediastinal ectopic tissue that may not have a connection to the normal cervical gland.[87] Surgical resection is recommended, as needle biopsy cannot rule out malignancy in such a large lesion, and substernal goiters will often cause symptoms of airway compression as they continue to grow. Nearly all substernal goiters can be removed via a cervical incision, although some do require a partial upper sternotomy.

Parathyroid Adenoma

The anterior mediastinum is the most common location for an ectopic parathyroid tumor. Often, ectopic parathyroid glands will present as persistent primary hyperparathyroidism after an unsuccessful neck exploration. Before proceeding with mediastinal exploration, localizing studies such as technetium-99m-sestamibi scintigraphy and CT are recommended. MRI may be useful to reveal well-defined masses; however, they are usually small (<3 cm). The adenoma is typically embedded within the thymus gland. Surgical resection of the adenoma, typically requiring resection of the thymus itself, is curative. We find the surgical technique of transcervical thymectomy, performed via the neck with a retractor lifting the sternum anteriorly, is ideal for this disease process and can be performed on an outpatient basis. VATS and/or robotic approaches also are applicable in this scenario.

MIDDLE MEDIASTINAL NEOPLASMS

Metastatic bronchogenic carcinoma is the most common etiology of middle mediastinal masses, as the mediastinal lymph nodes in the middle mediastinal compartment are a frequent site of lung cancer metastases. The most common primary masses of the middle mediastinum are lymphoma (described above) and benign cysts. Cysts constitute 12% to 20% of all primary mediastinal masses and are found chiefly in the middle compartment. These cysts comprise congenital foregut cysts, bronchogenic cysts, neurenteric cysts, and pericardial cysts and are reviewed in Chapter 81.

POSTERIOR MEDIASTINAL NEOPLASMS

Neurogenic tumors are the most common neoplasms of the posterior mediastinum, collectively representing 12% to 21% of all mediastinal masses and occurring almost exclusively (95%) in the posterior compartment.[88] Neurogenic tumors are categorized into three groups based on the neurogenic tissue of origin. Neoplasms arising from the nerve sheath include schwannoma, neurofibroma, and rarer malignant nerve sheath tumors. Nerve sheath tumors are the most common neurogenic tumors found in the adult. Neoplasms arising from the sympathetic ganglia include ganglioneuroma, ganglioneuroblastoma, and neuroblastoma, and these tumors are more commonly found in children. Neoplasms arising in parasympathetic ganglia include paraganglioma and chemodectoma, both of which also occur in the posterior mediastinum and are exceedingly rare. Approximately 98% of neurogenic mediastinal tumors in adults are benign, whereas it is estimated that more than 50% of neurogenic tumors in children are malignant.

Nerve Sheath Tumors

Schwannoma (neurilemmoma) and *neurofibroma* are the most common mediastinal neurogenic tumors.[89] Both of these are benign, slow-growing tumors. Most commonly, they appear as encapsulated and well-marginated masses found in the costovertebral sulci where they arise from intercostal nerve rami. Less frequently they can be found in the middle mediastinal compartment when they occur as tumors of the vagus or phrenic nerves. CT typically reveals a solitary, smoothly rounded mass in the upper half of either paravertebral sulcus abutting the vertebra (Fig. 82-7). An MRI should be employed to rule out intraspinal extension, if there is any possibility of this on CT.[90] Upon presentation, most patients are asymptomatic, although neurologic symptoms from intercostal nerve involvement or intraforaminal extension can be present.[91] Thus, many of these are identified as incidental findings on scans performed for other reasons. Over one-third of patients with neurofibromas will have neurofibromatosis (von Recklinghausen disease), and these patients tend to present at an earlier age and may have café au lait spots suggesting the diagnosis.[91,92]

Surgical resection is the definitive treatment for these benign nerve sheath tumors, and this can commonly be performed with VATS or robotic techniques with favorable results.[93,94] Excellent long-term survival is obtained with complete surgical excision of the tumors, and recurrence is uncommon.[88,93] However, additional neurofibromas or schwannomas may develop in patients with neurofibromatosis. Ten percent of these tumors extend through the intervertebral foramen and create a "dumbbell" appearance on imaging studies. For these lesions, combined thoracic (lateral) and neurosurgical (posterior) approaches can allow en bloc resection and can be achieved with low morbidity.[95] Typically this is accomplished with a posterior laminectomy followed by an anterior thoracoscopic approach.

Malignant nerve sheath tumors are essentially spindle cell sarcomas of the mediastinum and include malignant schwannoma, neurofibrosarcoma, and malignant neurofibroma. These tumors are rare, affect men and women equally in the third to fifth decades of life, and are highly associated with neurofibromatosis. Malignant schwannomas remain one of the most poorly characterized of all soft tissue sarcomas. In general, patients with malignant schwannomas present with large invasive tumors and have a poor prognosis. Complete surgical resection is rarely possible, and even when accomplished, local recurrence is common. Neurofibrosarcoma likely evolves from the malignant degeneration of a neurofibroma. Unlike benign nerve sheath tumors, patients with neurofibrosarcoma generally have symptoms of pain and nerve impingement.[96] On CT imaging, these tumors often appear as round masses with central areas of necrosis and hemorrhage. Radical surgical excision provides the only hope of cure; however, the 5-year overall survival rates are low (16% in patients with neurofibromatosis) and no survival benefit is gained by adjuvant chemotherapy.[96,97] Chemotherapy and radiotherapy are options for unresectable tumors.

Sympathetic Ganglion Tumors

Tumors of the sympathetic ganglia likely represent malignant degeneration of the nerve cell rather than the nerve sheath. These tumors are represented by the spectrum of ganglioneuroma, ganglioneuroblastoma, and neuroblastoma. In children, mature tumors such as ganglioneuroma occur in older individuals (median age, 7 years) and tend to behave in a benign fashion, whereas immature tumors such as neuroblastoma tend to occur in younger patients (median age, <2 years) and behave aggressively.[98]

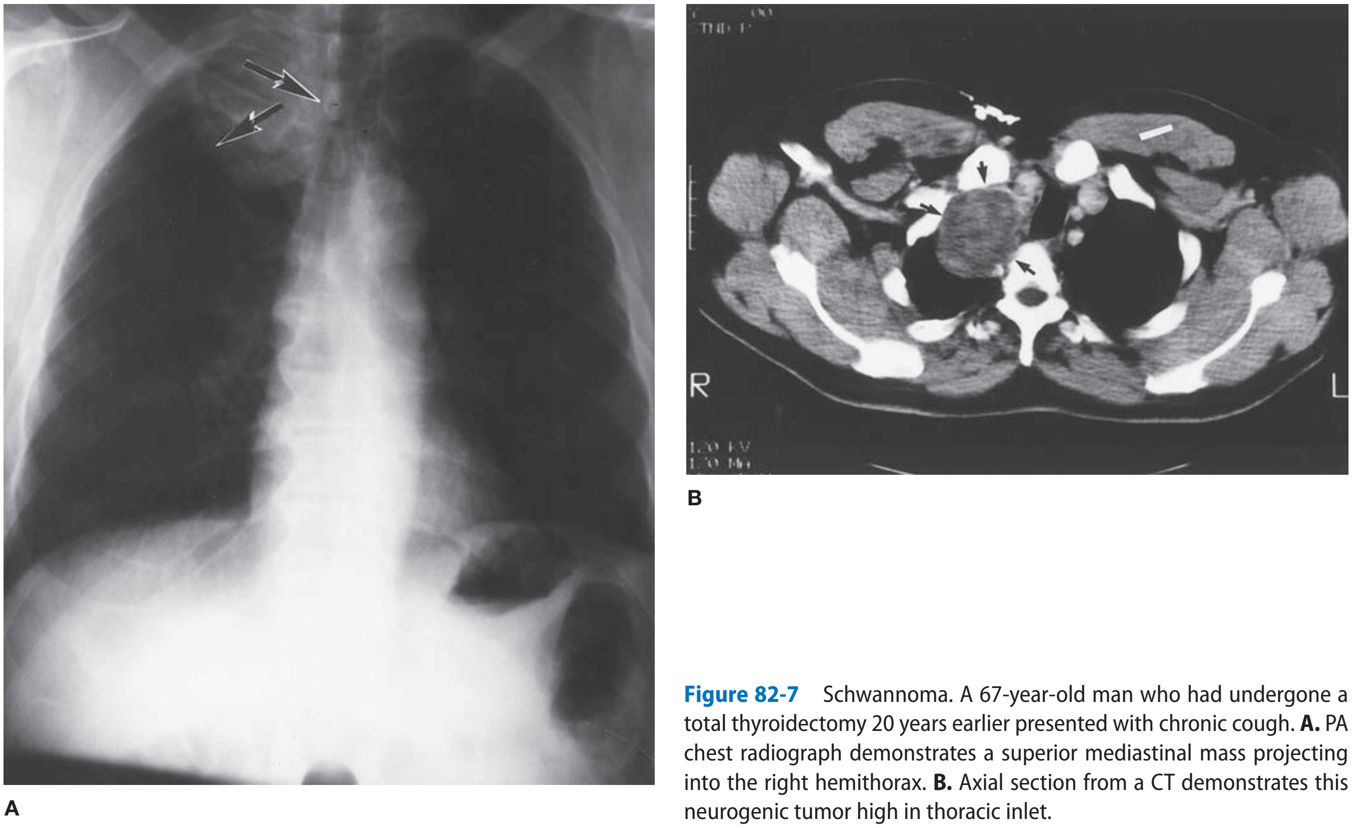

Figure 82-7 Schwannoma. A 67-year-old man who had undergone a total thyroidectomy 20 years earlier presented with chronic cough. **A.** PA chest radiograph demonstrates a superior mediastinal mass projecting into the right hemithorax. **B.** Axial section from a CT demonstrates this neurogenic tumor high in thoracic inlet.

Ganglioneuromas are the most benign type of sympathetic ganglion tumor. They are typically diagnosed in the second or third decade of life and are the most common neurogenic tumors occurring in childhood. Most patients with ganglioneuroma are asymptomatic upon presentation, although larger tumors may result in symptoms such as cough, dyspnea, dysphagia, chest pain, and Horner syndrome, and symptoms related to the secretion of catecholamines have been reported. Ganglioneuromas are generally large, well-circumscribed, and encapsulated tumors located in the paravertebral sulci. Surgical resection is a highly successful treatment for ganglioneuromas.[99]

Ganglioneuroblastoma is a tumor that demonstrates histologic elements similar to the well-differentiated ganglion cells seen in a ganglioneuroma as well as less-differentiated neuroblastoma-like features, and the degree of malignant behavior is related to the extent of the latter. Presentation is in the first decade of life, and both sexes are equally affected. Approximately half of patients will present with symptoms. Most children present with a solitary mass that is amenable to complete surgical resection. The treatment of ganglioneuroblastoma is primarily surgical, although chemotherapy is indicated in intermediate and high-risk groups. Overall these tumors are associated with relatively high 5-year survival rates, reported to be 88% in one large series.[100]

Neuroblastomas are the most malignant of the sympathetic ganglion tumors. These highly aggressive and readily metastasizing tumors are found almost exclusively in children, with 95% occurring in patients less than 5 years old.[101] Most patients present with symptoms that include chest pain, dyspnea, myelopathy from spinal canal involvement, and symptoms of excess catecholamine production. Distant metastases are common.[102] On CT, mediastinal neuroblastomas appear as elongated paraspinous masses often impinging on adjacent structures and causing bony destruction. Eighty percent of tumors demonstrate calcification.[103] MRI is useful for determining nodal, chest wall, and intraspinal involvement. The International Neuroblastoma Staging System (INSS) is the most commonly used staging system for this disease. It includes factors such as tumor size, lymph node metastases, and extent of unresectable disease and can be used to predict survival.[104] Amplification of the oncogene N-myc has additionally been shown to correlate with worse prognosis.[105] The treatment of neuroblastoma depends primarily on stage. For patients with stage I disease, resection alone is usually curative.[106,107] For patients with partially resectable stage II and III diseases, surgical resection is followed by postoperative multiagent chemotherapy. Patients with stage IV disease are generally treated with chemotherapy and radiation.

■ Neoplasms Arising in Parasympathetic Ganglia

Paragangliomas are rare tumors that arise from specialized neural crest cells associated with autonomic ganglia, called paraganglia. Paragangliomas can be categorized into two groups based upon association with either the parasympathetic system or the sympathetic system. Parasympathetic paragangliomas do not secrete catecholamines and were previously called chemodectomas. They may arise from mediastinal chemoreceptors including the aortopulmonary glomus or anywhere along the vagus nerve and are chromaffin-negative tumors. Tumors connected with the sympathetic nervous system are divided into functional paragangliomas and nonfunctional paragangliomas based on their ability to secrete catecholamines. These tumors were previously called extra-adrenal pheochromocytomas.

Both genders are equally affected by mediastinal paragangliomas, usually in the third or fourth decade of life. The clinical presentation includes symptoms of local mass effect as well as varying degrees of hypertension and hypermetabolism secondary to the production of epinephrine and norepinephrine. Excess plasma and urinary levels of catecholamines can often be detected. Preoperative localization is essential. CT, MRI, and echocardiography can be useful for anatomic imaging, and functional imaging studies such as ^{131}I-metaiodobenzylguanidine (MIBG) scintigraphy can be used to localize lesions not seen on other scans. Treatment requires surgical excision, and presurgical conditioning with alpha and then beta blockade is usually necessary for functional lesions to prevent severe hypertension intraoperatively.[108]

OTHER MEDIASTINAL TUMORS

Additional neoplasms of the mediastinum include those seen in Castleman's disease and a variety of mesenchymal tumors.

Castleman Disease

Castleman disease is a rare lymphoproliferative disorder that can involve enlargement of one (unicentric Castleman disease) or multiple (multicentric Castleman disease) lymph nodes. Most adults with unicentric disease are asymptomatic. The mediastinum is the most common location of unicentric disease, and lesions most frequently occur in the anterior and middle mediastinal compartments.[109,110] Multicentric Castleman disease is characterized by peripheral lymphadenopathy and hepatosplenomegaly; a subset of patients also demonstrates mediastinal and intra-abdominal adenopathy. Multicentric Castleman disease is classified as human herpesvirus 8 (HHV-8) associated, typically occurring in immunocompromised patients, and as HHV-8-negative or idiopathic multicentric Castleman disease.

Castleman disease is categorized into two histologic types (hyaline vascular and plasma cell), but the centricity rather than histology is more important in predicting long-term outcome. Complete surgical resection should be performed in unicentric disease and is associated with greater than 95% overall survival and greater than 80% disease-free survival at 5 years.[110] Multicentric Castleman disease can be rapidly progressive and often fatal, and the role of surgery is primarily to obtain tissue to establish a diagnosis, with the treatment being systemic therapy. Castleman disease can mimic many other mediastinal tumors and must be kept in mind as a rare possible diagnosis.

Mesenchymal Tumors

A variety of mesenchymal tumors constitute approximately 6% of all tumors that occur in the mediastinum.[3] More than half of these lesions turn out to be malignant. A large variety of categories exist for mesenchymal tumors of the mediastinum, and their spectrum runs the entire gamut of soft tissue tumors, including but not limited to adipocytic tumors (lipoma, lipomatosis, liposarcoma), vascular tumors (hemangioma, lymphangioma), fibroblastic tumors (fibrous tumors), smooth muscle tumors (leiomyoma, leiomyosarcoma), skeletal muscle tumors (rhabdomyoma, rhabdomyosarcoma), and chondro-osseous tumors (chondrosarcoma, osteosarcoma). Their management is similar to that of extrathoracic soft tissue tumors, with resection indicated if possible.

PART 11

Disorders of the Chest Wall, Diaphragm, and Spine

83 **Nonmuscular Diseases of the Chest Wall** 1440
84 **Effects of Neuromuscular Diseases on Ventilation** 1459

CHAPTER 83

Nonmuscular Diseases of the Chest Wall

George E. Tzelepis
F. Dennis McCool

INTRODUCTION

The chest wall is a major component of the respiratory pump and consists of the rib cage and abdomen. It is inflated by the inspiratory muscles of the rib cage and the diaphragm, and its integrity is key to sustaining ventilation. Disorders affecting the nonmuscular structures of the chest wall (the thoracic spine, ribs, costovertebral joints, abdominal wall, and sternum) may lead to respiratory dysfunction. When the integrity of these nonmuscular components is severely compromised, respiratory failure may ensue. The pathophysiology of disorders affecting these nonmuscular components is generally related to the imposition of excessive elastic loads placed on the respiratory muscles. In some disorders, such as kyphoscoliosis and obesity, the load on the respiratory muscles is chronic and progressive. By contrast, with flail chest, the load on the respiratory muscles is acute. If the respiratory muscles have not adapted or had little time to adapt to loads that increase the work of breathing, respiratory failure may quickly ensue. Other disorders, such as ankylosing spondylitis and pectus excavatum, have a minimal impact on respiratory function. The respiratory muscles are discussed in Chapters 3 and 142.

KYPHOSCOLIOSIS

Kyphoscoliosis (KS) refers to a three-dimensional spinal deformity characterized by excessive curvature of the spine in the lateral plane (scoliosis) and sagittal plane (kyphosis), as well as by vertebral axis rotation.[1] Scoliosis, defined as a lateral curvature greater than 10 degrees, is generally associated with kyphosis and spinal axis rotation.[2,3] KS is one of the most common spinal abnormalities, with estimates of prevalence in the United States ranging from 1 in 10,000 people for severe deformities to 1 in 1000 people for mild deformities.[4] It is classified as idiopathic (no known cause), secondary or paralytic (due to neuromuscular disease), or congenital (associated with vertebral malformation at birth) (Table 83-1).[5]

Etiology and Diagnosis

Idiopathic KS usually manifests in late childhood or early adolescence and involves primarily females (ratio of 4:1).[2,5] Although largely unknown, the cause of the idiopathic KS likely includes a combination of genetic and environmental factors, which through abnormal bone, muscle growth, or hormonal imbalance lead to increased spine curvature.[6] Idiopathic KS is believed to be a multigene condition of autosomal or sex-linked inheritance with variable phenotypic expression.[2] Individuals with idiopathic KS may complain of back pain or may have psychological problems.[2] When KS is severe, complaints include dyspnea with exertion and constitutional symptoms related to nocturnal hypoventilation. Respiratory failure also may develop.[7]

Paralytic or secondary KS may be due to a number of neuromuscular disorders including polio, muscular dystrophy, cerebral palsy, and spinal bifida.[5] With these diseases, KS typically occurs when the individuals become nonambulatory. Congenital KS results from developmental vertebral anomalies that are usually present at birth.[8] Although uncommon, it can lead to serious neurologic complications such as paraplegia.

The diagnosis of KS is readily made by physical examination and radiologic assessment. In severe KS, physical examination typically reveals a dorsal hump due to angulated ribs and shoulder asymmetry. In addition, there may be "hip tilt" related to spinal rotation (Fig. 83-1A). In mild KS, subtle changes in spinal curvature may be elicited by performing the *Adam's forward bend test*. With this test, the patient bends forward at the waist with feet together and knees straight, until the spine becomes parallel to the floor. The observer, then, examines for thoracic and lumbar region symmetry from behind and alongside the patient.

Radiographic studies (upright PA and lateral views of the spine) are used to confirm the diagnosis, and to assess severity by measuring the *Cobb angle* on the coronal or sagittal plane of imaging.[9] This is the angle formed by the intersection of two lines, each of which is parallel to the top and bottom vertebrae of the scoliotic or kyphotic curves (Fig. 83-1B). The greater the Cobb angle, the more severe the deformity. Cobb angles less than 60 degrees are generally not associated with ventilatory impairment; those greater than 100 degrees are invariably associated with respiratory symptoms, and those greater than 120 degrees with respiratory failure.[10,11] Among symptoms, dyspnea on exertion typically progresses with age and the degree of spinal deformity. Sequential radiographic studies are useful in evaluating progression of the spinal deformity.

Respiratory Mechanics

Severe restrictive respiratory impairment is the pathophysiologic feature of KS. Specifically, respiratory system compliance is reduced,

and the pressure required to inflate the lungs at any given volume is greater than in a healthy individual. Consequently, functional residual capacity (FRC) is invariably decreased, the elastic load placed on the respiratory muscles is increased, and the work of breathing is significantly increased.[12]

In KS, reduced respiratory compliance is primarily related to a decrease in chest wall compliance and to a lesser extent to a decrease in lung compliance resulting from microatelectasis.[7,13] The respiratory pressure-volume relationship is shifted to the right, thus requiring greater than normal pressures to inflate the lungs (Fig. 83-2). In addition, the straight portion of the pressure-volume curve, where compliance is fairly constant in the normal individual, is diminished, largely due to a significantly decreased total lung capacity (TLC). The poorly distensible chest wall reduces the resting position of the respiratory system (FRC), and tidal breathing occurs on a flatter portion of the pressure-volume curve.[7] Greater inspiratory effort is needed for relatively small tidal breaths, which increases the work of breathing. The increase in the oxygen cost of breathing may reach values 3 to 5 times greater than those measured in healthy individuals and thus places patients at risk for respiratory muscle fatigue.[14,15]

In idiopathic KS, the compliance of the chest wall and respiratory system both decrease as the Cobb angle increases (Fig. 83-3), with the most pronounced reductions in chest wall compliance seen in individuals with Cobb angles greater than 100 degrees. Cobb angles up to 50 degrees do not significantly decrease respiratory system compliance.[12]

The reduction in chest wall compliance promotes breathing with shallow tidal breaths, and the reduction in FRC leads to breathing at low lung volumes. Both factors predispose to the development of atelectasis and may thus reduce lung compliance. Although lung compliance may be diminished, it is not as severely reduced as chest wall compliance.[13] Since chest wall compliance decreases with age,[16] respiratory mechanics invariably deteriorate with age even in the absence of spinal deformity progression.[17]

Respiratory muscle strength, as measured by the maximal static inspiratory (PI_{max}) and expiratory pressure (PE_{max}), is generally normal in individuals with idiopathic KS and Cobb angles of less

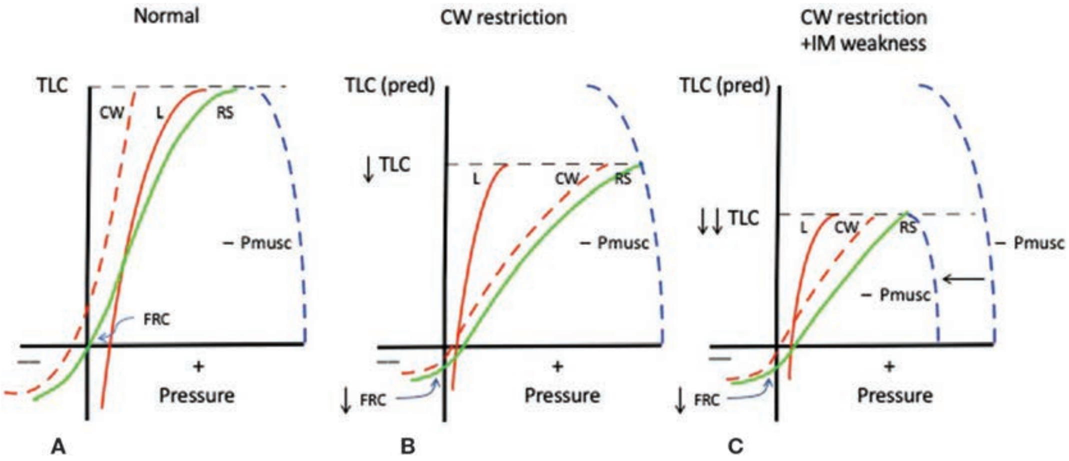

Figure 83-2 Schematic showing the volume-pressure relationships of the chest wall (CW), lung (L), and respiratory system (RS) for (**A**) healthy individuals, (**B**) individuals with chest wall restriction, and (**C**) individuals with chest wall restriction complicated by inspiratory muscle (IM) weakness. In panel **B**, the reduced chest wall compliance lowers respiratory system compliance, FRC, and TLC. In panel **C**, maximal inspiratory muscle pressures (P_{mus}) are half of predicted and the restriction is amplified by the presence of IM weakness.

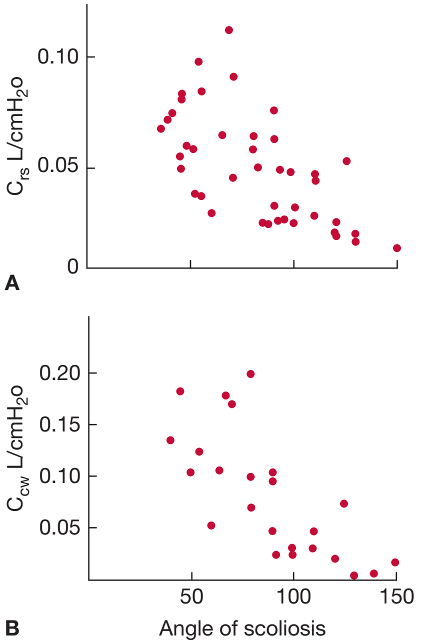

Figure 83-3 Relationship between (**A**) the angle of scoliosis and compliance of the total respiratory system and (**B**) the angle of scoliosis and compliance of the chest wall in patients with idiopathic scoliosis. *(Reproduced with permission from Kafer ER: Mechanical properties of the respiratory system and the ventilatory response to carbon dioxide. J Clin Invest. 1975;55(6):1153–1163.)*

than 50 degrees. With Cobb angles greater than 50 degrees, PI_{max} and PE_{max} may be mildly to moderately reduced and accompanied by only a mild decline in vital capacity (VC).[18] In idiopathic KS, reductions in PI_{max} may be due to mechanical disadvantage of the respiratory muscles coupled to a distorted rib cage.[19] In secondary KS, however, reductions in PI_{max} are related to intrinsic muscle weakness.[20]

The reductions in VC in idiopathic KS are typically seen in patients with severe spinal deformities (Cobb angles greater than 100 degrees). In this setting, TLC and VC may be reduced to 30% of predicted[11,17] (Fig. 83-4). Forced vital capacity (FVC) decreases in proportion to the reduction in TLC in the absence of obstructive airway disease. Residual volume (RV) may be normal or slightly increased, resulting in a relatively high RV/TLC ratio.[21] In mild and moderate KS (i.e., Cobb angles less than 60 degrees), VC and TLC may be only mildly reduced. Although uncommon, obstructive airway dysfunction in nonsmokers has been described.[22] This includes reductions in mid-expiratory flow rates or FEV_1 related to torsion or compression of major bronchi from the distorted spine[23,24] (Fig. 83-5).

Factors other than Cobb angle can contribute to the reduction in TLC and VC. These factors include the location of the spinal curve (thoracic vs. lumbar), number of vertebrae involved, patient's age, degree of spinal rotation, and, most importantly, the presence or absence of inspiratory muscle weakness. Coexistent respiratory muscle weakness significantly affects the severity of restriction. In the paralytic type of KS, the degree of lung restriction is primarily determined by the magnitude of respiratory muscle weakness rather than by the degree of spinal curvature.[20] Thus, for a similar Cobb angle, patients with paralytic KS are likely to have greater pulmonary function impairment than patients with idiopathic KS.[20] In patients with congenital KS, coexisting rib deformities or underlying lung abnormalities similarly lead to a greater loss in VC for a given degree of spinal deformity than seen in patients with idiopathic KS.[25]

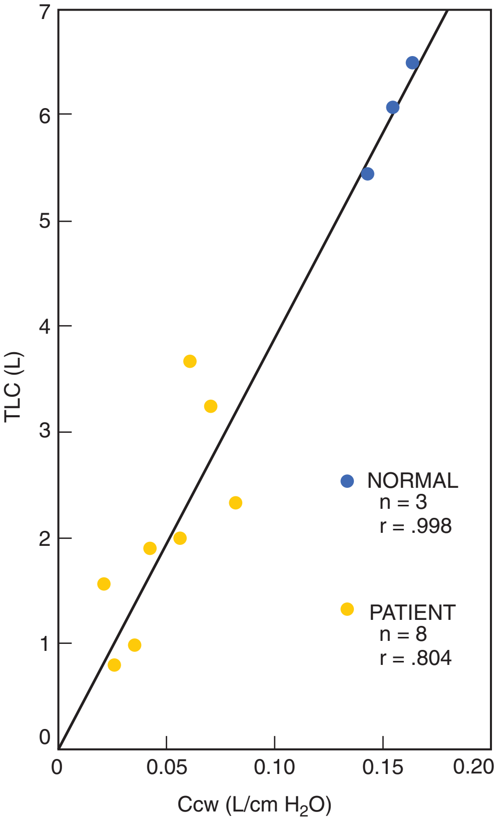

Figure 83-4 The reduction in total lung capacity (TLC) in kyphoscoliosis is related to the reduction in chest wall compliance (CCW). *(Data from Ting EY, Lyons HA. The relation of pressure and volume of the total respiratory system and its components in kyphoscoliosis. Am Rev Respir Dis. 1964;89:379–386.)*

The work of breathing is increased in KS largely due to increased elastic load related to the stiff chest wall.[12] Consequently, the oxygen cost of breathing may be three to five times that seen in healthy subjects. Concomitant inspiratory muscle weakness decreases ventilatory reserve and predisposes the respiratory muscles to fatigue and contributes to respiratory failure in these patients.[26]

■ Exercise Capacity

In KS with Cobb angles greater than 60 degrees exercise capacity may be severely limited. Typically, maximal oxygen consumption is reduced to about 60% to 80% of predicted, heart rate is higher per workload, the ratio of tidal volume to vital capacity (VT/VC) is greater than 0.5, and the ratio of maximum exercise ventilation to maximum voluntary ventilation ($\dot{V}E_{max}$/MVV) can reach 0.7. Decreased respiratory system compliance, increased work of breathing, and respiratory muscle weakness all contribute to poor exercise capacity.[27,28] Concomitant pulmonary hypertension in those with Cobb angles >100 degrees may independently contribute to exercise limitation.

In individuals with mild to moderate spinal curves (Cobb angles 20–45 degrees), poor exercise tolerance with reduction in $\dot{V}O_{2max}$ is usually due to limb muscle deconditioning rather than to ventilatory constraints.[29]

■ Control of Breathing

Individuals with severe KS compensate for the increased elastic loads on the inspiratory muscles by adopting a rapid shallow breathing pattern consisting of low tidal volumes, shortened inspiratory time (T_I), and an increased respiratory rate (i.e., reduced total breath

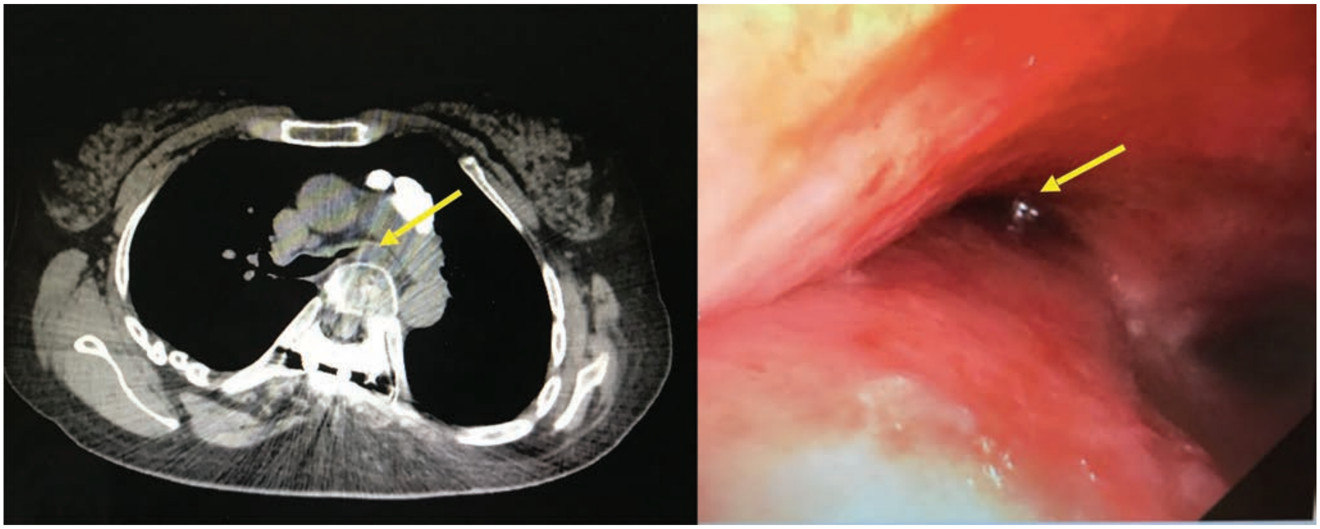

Figure 83-5 Chest CT and bronchoscopic images of extrinsic compression of the left mainstem bronchus *(arrows)* due to distorted spine in kyphoscoliosis.

time, T_{TOT}).[26,30] In young patients with KS and normal blood gases, T_I and duty cycle (T_I/T_{TOT}) correlate negatively with the angle of scoliosis.[30] In the setting of reduced respiratory system compliance, this breathing pattern minimizes the work per breath and the pressure needed to inhale, thus lessening the likelihood of developing inspiratory muscle fatigue and respiratory failure. The disadvantage of a rapid shallow breathing pattern is an increase in dead space ventilation, which reduces alveolar ventilation, causes hypoxemia, promotes atelectasis through airway closure, and further decreases lung compliance.[31]

Another strategy to compensate for the increased elastic loads is by increasing neural drive to the respiratory muscles.[30] Indirect measurements of the neural drive to the respiratory muscles, such as mouth occlusion pressure at 100 ms (P0.1) measured during quiet breathing, exercise, or breathing stimulated by hypercapnia, are usually elevated in these individuals and correlate positively with the angle of deformity.[30] The increase in neural drive is not necessarily associated with increased alveolar ventilation, as the stiff chest wall and the weak respiratory muscles will limit any augmentation in alveolar ventilation.

■ Sleep Disordered Breathing

Nocturnal hypoventilation commonly occurs in severe KS and classically precedes the development of chronic hypercapnia.[17,31] While awake, individuals with Cobb angles >100 degrees can maintain adequate alveolar ventilation by increasing neural drive to the diaphragm and recruiting accessory inspiratory muscles.[26,30] However, during sleep, neural drive to the inspiratory muscles is diminished, especially during REM sleep.[32] Since these patients are dependent exclusively on the diaphragm to maintain alveolar ventilation in REM sleep, they are at risk for becoming hypercapnic and hypoxemic. The risk of hypoventilation is amplified if there is diaphragm dysfunction.[33] Of interest, the magnitude of nocturnal hypoventilation may not correlate with the degree of thoracic deformity, pulmonary function testing, or neural drive to the respiratory muscles.[33] This observation suggests that inspiratory muscle weakness may be a more important factor for developing nocturnal hypoventilation. Persistent nocturnal desaturation and hypercapnia may further weaken the respiratory muscles, aggravate hypoxemia, and lead to pulmonary hypertension and cor pulmonale. Obstructive sleep apnea, which has a similar prevalence in KS to that of the general population, also may complicate nocturnal hypoventilation.[34] Since nocturnal hypoventilation is treatable and typically occurs before the onset of cardiorespiratory failure, the clinician must be aware of the sleep breathing abnormalities in these patients and promptly diagnose them with overnight polysomnography.[34]

■ Gas Exchange

Abnormalities in gas exchange frequently exist in patients with KS, with normocapnic hypoxemia being the most common abnormality. In nonsmokers with idiopathic KS, Pa_{O_2} correlates directly with VC and inversely with the angle of scoliosis. The age-dependent decrease in Pa_{O_2} is greater than that of normal individuals, and oxyhemoglobin desaturation can occur with minimal activity.[7,17] Hypoxemia is primarily due to ventilation/perfusion mismatch and less often to intrapulmonary shunt associated with atelectasis.[35] In severe KS with chronic hypercapnia, hypoventilation also contributes to hypoxemia. Hypercapnia initially occurs only during sleep or with exercise.[17] With aging or as the disease progresses, hypercapnia is seen at rest while awake.

■ Clinical Course

The natural history of KS largely depends on underlying etiology and degree of spinal deformity. Congenital KS with severe spinal deformities may progress rapidly, resulting in marked restrictive dysfunction, cor pulmonale, and early death.[36] Secondary KS may also progress to develop severe restrictive dysfunction and cardiorespiratory failure.[37] In general, when KS manifests early in life (age 0–8 years) there is a greater risk for rapid progression of the spinal deformity during growth, continued progression of the deformity after skeletal maturity, and development of respiratory failure.[37]

In contrast, idiopathic KS typically has an overall benign course. If the spinal deformity at skeletal maturity is mild, these individuals have an excellent prognosis with little respiratory impairment, and an overall good quality of life.[2] In individuals with idiopathic KS and moderate or severe deformity at presentation (age 12–16 years), the risk of deformity progression and development of respiratory impairment increases significantly.[2] Risk factors for deformity progression generally include large curves at presentation, skeletal immaturity, and curves with a thoracic apex.[2] By rough estimates, individuals with thoracic deformities greater than 50 degrees at skeletal maturity are at risk for a progressive increase in the spinal curve at a rate of about 1 degree annually.[10]

Most young individuals with idiopathic KS are asymptomatic. As deformity progresses with aging, many will develop back pain and dyspnea. Initially, dyspnea may occur only with activities and eventually be present at rest.[17] Consequently, older individuals with severe idiopathic KS, especially those with a Cobb angle >110 degrees and VC of <45% predicted, should be monitored for respiratory complications.[17] When cardiorespiratory failure develops, the prognosis is poor, and without supplemental oxygen or ventilatory support death may occur within 1 year. The risk of respiratory failure is even greater in patients with inspiratory muscle weakness, sleep-disordered breathing, obesity, or bronchial compression and central airway obstruction by the distorted vertebrae. Pregnancy generally does not increase the risk for respiratory failure; however, women with idiopathic KS and a VC of less than 1 L may develop respiratory problems during pregnancy.[38]

■ Treatment

General measures for adults with KS include smoking and vaping cessation, maintenance of a normal body mass index, frequent physical activity to improve exercise tolerance and minimize deconditioning, routine vaccinations, prompt treatment of respiratory infections, and psychological support for those with diminished self-image. Supportive therapy with supplemental oxygen during activity or sleep may be needed if there is evidence of oxyhemoglobin desaturation with exertion or sleep. Domiciliary oxygen therapy may be sufficient if it corrects nocturnal hypoxemia without inducing hypercapnia. However, hypercapnia needs to be closely monitored, especially in individuals with a VC less than 50% of predicted. If hypercapnia is present, nocturnal noninvasive ventilatory support should be initiated. Dyspnea, morning headaches, poor sleep quality, fatigue and the presence of cor pulmonale are symptoms and signs that should alert the clinician to the presence of nocturnal hypoventilation.[39] Long-term, nocturnal noninvasive ventilation should be offered to all patients with KS and chronic hypercapnic respiratory failure, as it reduces mortality.[39–42]

Noninvasive positive-pressure ventilation can be delivered via a nasal mask or full-face mask, with or without supplemental oxygen. When prescribing a positive pressure device, either a pressure- or volume-preset ventilator can be used.[43] Apart from the potential for greater leakage with the pressure mode, pressure or volume ventilation have equivalent beneficial effects on physiologic and clinical parameters as well as overall health status. Contraindications to noninvasive ventilation include the inability to protect the upper airway due to impaired cough, excessive airway secretions, or inability to cooperate.[39] When noninvasive ventilation has failed or is contraindicated, invasive ventilation should be considered.

The benefits of noninvasive ventilation include improvements in gas exchange, sleep efficiency, pulmonary hemodynamics, respiratory drive, quality of life, and survival (Table 83-2).[39,42] By contrast, measurements of VC, PI_{max}, twitch transdiaphragmatic pressure, and respiratory muscle endurance are not usually improved by noninvasive ventilation.[44] Accordingly, the lower incidence of respiratory failure in patients undergoing positive-pressure ventilation may be attributed to improvements in respiratory control rather than improvement of respiratory muscle contractility.[44] Long-term noninvasive ventilation substantially reduces the number of hospitalizations for respiratory failure and the length of hospital stay.[39] Survival benefit of KS patients treated with noninvasive ventilation and supplemental oxygen over those patients treated with just oxygen has been demonstrated by comparative and observational studies (Fig. 83-6).[40–42,45]

Operative and nonoperative (brace) approaches in skeletally immature children with idiopathic KS have been used to prevent or delay the deformity progression. A brace is generally used in growing children with angles between 25 and 45 degrees,[46] and surgery is recommended for adolescents with angles greater than 45 to

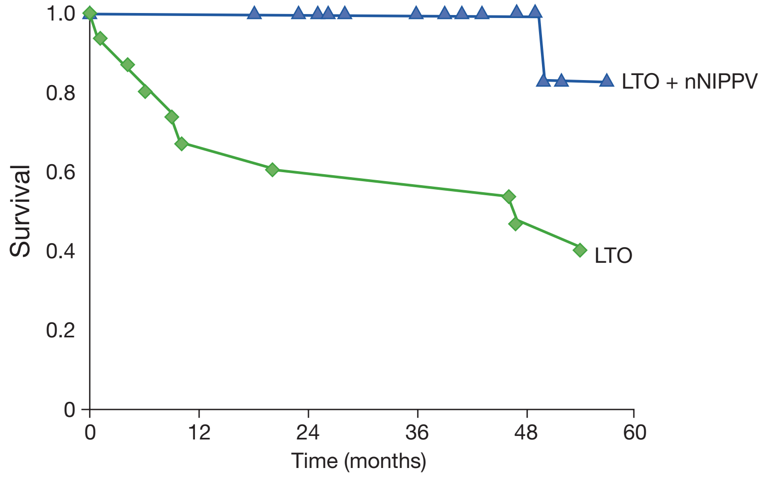

Figure 83-6 Survival curves of kyphoscoliotic patients treated with long-term oxygen therapy (LTO) or LTO and nocturnal nasal intermittent positive-pressure ventilation (nNIPPV). *(Reproduced with permission from Buyse B, Meersseman W, Demedts M: Treatment of chronic respiratory failure in kyphoscoliosis:oxygen or ventilation? Eur Respir J. 2003;22(3):525–528.)*

50 degrees.[3,47] Of the surgical techniques, fusion of the affected vertebrae with rod fixation to the spine is accomplished via the posterior or anterior approach. Spinal fusion has considerable disadvantages, as it has been associated with restrictive respiratory defects, decreased ability to carry out daily activities, and poor cosmetic results.[48] In young children (age <10 years), severe restrictive respiratory disease (VC <50% of predicted) may occur in roughly 50% of patients undergoing spinal fusion, especially in those with extensive thoracic fusions or in those with fusions of the proximal thoracic spine.[48] Surgical fusion of the spine may have a role in children with congenital spinal deformities or in children with KS secondary to neurologic defects.[49] Newer nonfusion approaches include implantation of growth-friendly rods such as expandable spinal rods, titanium rib implants, or remotely distractible magnetically controlled rods.[50] These latest techniques permit control of spinal deformity while allowing continued spinal growth and pulmonary development.[50] In the absence of randomized controlled studies, the overall efficacy of bracing or surgery in restoring pulmonary function to that of nonscoliotic individuals and minimizing the possibility of respiratory failure is not clear.[2,3,51]

THORACOPLASTY

Thoracoplasty refers to a surgical procedure aimed to reduce the volume of a hemithorax. In the pre–antituberculous chemotherapy era, thoracoplasty was the standard operative approach to control cavitary pulmonary tuberculosis. It consisted of different combinations of rib removal, rib fracture, phrenic nerve resection, or lung compression by filling the pleural space with foreign material (e.g., ping pong balls) (Fig. 83-7). Since the procedure was largely performed in the 1940s and 1950s, very few people who had undergone the procedure are still alive.[52] Historically, these individuals commonly developed dyspnea, severe restrictive dysfunction, and chronic hypercapnic respiratory failure as they aged.[52] The severity of the restrictive defect was often comparable to that seen in KS (Tables 83-3 and 83-4) and was related to the number of ribs removed, presence of fibrothorax, lung fibrosis secondary to underlying granulomatous disease, prior lung resection, or intentional phrenic nerve damage.[52] As in most restrictive chest wall diseases, these patients had impaired gas exchange, limited exercise tolerance, and an increased oxygen cost of breathing, and they eventually would develop cor pulmonale. Progressive scoliosis with aging further impaired respiratory function. Although this procedure is of historic interest, the purpose of reviewing thoracoplasty in this chapter is that the procedure is still occasionally performed. Currently, thoracoplasty is indicated for treatment of bronchopleural fistulae that have failed to close following decortication or for treatment of persistent empyema in which decortication is not feasible or has failed to eradicate the infection (Fig. 83-7).[53] Treatment of individuals who are post-thoracoplasty and have developed restrictive disease consists of supplemental oxygen, antibiotics for respiratory infections, and noninvasive ventilatory support.

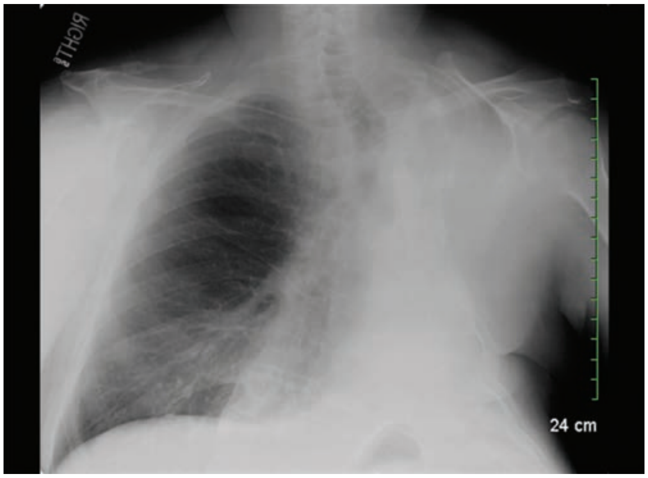

Figure 83-7 Chest radiograph of a patient who is post-thoracoplasty as part of the treatment of postpneumonectomy empyema. *(Reproduced with permission from Borges N, Saha S. Thoracoplasty for Postpneumonectomy Empyema Associated with Bronchopleural Fistula: A Case Series. Int J Angiol. 2015;24(2):151–154.)*

PECTUS EXCAVATUM

Pectus excavatum, also known as funnel chest, is a congenital chest wall deformity characterized by excessive depression of the sternum and the adjacent ribs producing a caved-in appearance to the rib cage.[54] It is the most common congenital deformity of the chest wall, with a prevalence of about 1 in 1000 live births and a male-to-female ratio of 3 to 1.[55] A family history may be present in up to 40% of cases.[56] Based on chest CT measurements, a recent large, population-based, multiethnic cohort study found a pectus excavatum prevalence of 0.4% or 1 in 250 adult individuals (median age 45 years).[57]

■ Etiology and Clinical Features

Although its pathogenesis is unknown, pectus excavatum is believed to result from an abnormal growth of cartilage around the sternum due to a defect in collagen formation.[58] In support of this mechanism is the relatively high prevalence of pectus excavatum in Marfan syndrome, Ehlers-Danlos syndrome, and Noonan syndrome.[59] Additionally, up to 40% of these individuals have scoliosis.[60]

Although occasionally present at birth, pectus excavatum typically becomes visible in early childhood and during the adolescent growth

TABLE 83-4 Respiratory Mechanics in Diseases of the Chest Wall

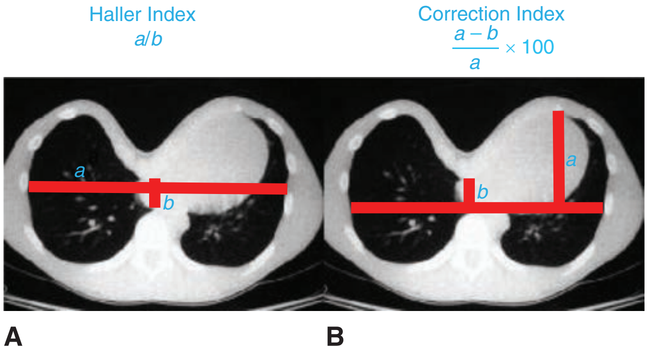

Figure 83-8 Chest computed tomography of a patient with pectus excavatum. The Haller index is the ratio of the transverse to anterior-posterior (AP) diameters of the rib cage at the level of the deepest sternal depression. (**A**) The difference between the minimum distance used to calculate the Haller index, and the distance between the anterior spine and the most anterior portion of the chest is used to calculate the correction index. (**B**) The difference of the two distances is divided by the maximum distance and expressed as a percentage.

spurt. The sternal depression may be minimal or prominent. The most frequent complaints of individuals with pectus excavatum are usually cosmetic. The psychological impact of the pectus deformity becomes more troublesome during the teenage years when body image becomes more important.[56] Exertional dyspnea and exercise intolerance may occur in 30% to 70% of patients.[61] However, these symptoms cannot be entirely explained by the mild restrictive pattern that is sometimes seen (Table 83-3) or by limitations in cardiac output. Adults with pectus excavatum also may experience daily physical and psychosocial symptoms and complain of poor sleep quality.[62,63]

The degree of sternal depression and the percentage of the chest that needs to be corrected are assessed by calculating the Haller index and the correction index, respectively, from chest CT images. The Haller index is the ratio of the transverse to anterior-posterior (AP) diameters of the rib cage at the level of the deepest sternal depression (Fig. 83-8A).[58] In normal individuals this ratio is about 2.5. A ratio greater than 3.25 is considered significant sternal depression.[58] The correction index uses the difference of two distances, a minimum and a maximum (Fig. 83-8B). The minimum distance is that used to calculate the Haller index, and the maximum distance is that between the anterior spine and the most anterior portion of the chest. The difference of the two distances is divided by the maximum distance and expressed in percentage.[64] Normal correction index is 10% or less.[54]

Pathophysiology

Severe pectus deformities may be associated with mild reduction in TLC and VC, especially with a Haller index of 5 or higher.[65] With concomitant scoliosis, the restriction may be more pronounced. Although obstructive defects are infrequent (approximately 2% of cases),[61,65] RV and the RV/TLC ratio are commonly increased. The elevated RV and RV/TLC may be due to stiffness of the rib cage resulting in reduced chest wall compliance in these young individuals rather than air trapping or expiratory muscle weakness. In most cases there is no underlying lung disease, and lung compliance is normal. Unlike ankylosing spondylitis, the mobility of the rib cage is not impaired at rest or during exercise in pectus excavatum.[66,67]

Cardiopulmonary exercise testing is usually normal in individuals with pectus excavatum. Indices such as maximal work rate, maximum oxygen consumption, and maximal oxygen pulse are not different from those of healthy individuals. In severe deformities, limited exercise capacity with reductions in maximal work rate or oxygen consumption at a given work rate may occur and often are out of proportion to the mild restrictive respiratory impairment found in these patients.[68] The explanation for the limited exercise capacity in this group of patients may be a reduction in venous return to heart associated with right ventricular compression due to sternal depression. Distortion of right ventricular geometry may be detected by echocardiographic (Fig. 83-9) or cardiac magnetic resonance imaging studies.[69] However, the role of these findings in limiting exercise capacity is not entirely known.

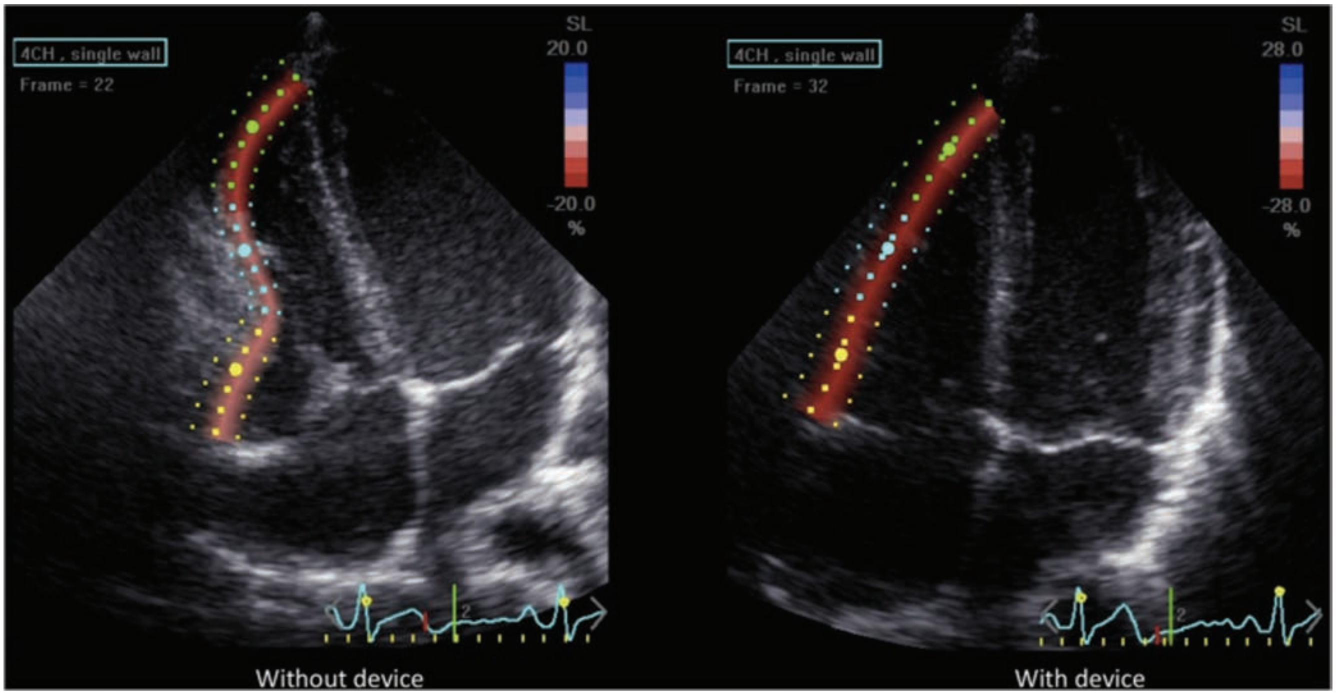

Figure 83-9 Four-chamber echocardiogram showing compression of the right ventricular free wall (red dotted line) by the pectus deformity, which is reversed by applying negative suction to the chest wall. *(Reproduced with permission from van Schuppen J, de Beer SA, van der Hulst AE, et al. Impact of vacuum bell on thoracic shape and cardiac function in pectus excavatum. J Cardiovasc Comput Tomogr. 2018;12(5):e17–e19.)*

Treatment

Conservative treatment with a vacuum bell for a minimum of one hour daily can be used in selected patients with pectus excavatum. With this device, better outcomes were noted in individuals with age less than 11 years, chest depth less than 1.5 cm, and chest wall flexibility.[70]

Although surgery is most often performed for cosmetic reasons, it is clearly indicated when the deformity has significant physiologic and psychological repercussions for the individual.[71] The optimal timing for repair is around 10 to 14 years of age or at a younger age if there is significant cardiopulmonary compromise. Individuals selected for repair typically have a Haller index greater than 3.25 or a correction index of more than 20%.[64,71]

The most common surgical approaches include modifications of the open-resection method originally described by Ravitch or the minimally invasive approach described by Nuss.[58] The first method involves resection of costal cartilage and a sternal osteotomy, with or without fixation of the sternum by external or internal supports. This procedure may be complicated by sternal necrosis, infection, or recurrence of the deformity. Recurrence may arise in younger children in whom sternal supports are not used. The invasive approach is best suited for older adults and for individuals with combined pectus excavatum and carinatum, marked asymmetry, or extensive defects involving the upper ribs.[58]

The Nuss procedure, developed in the 1990s, provides a minimally invasive alternative to reconstructing the deformity.[72] It consists of placing a curved metal bar under the sternum at the point of deepest depression through small incisions made on each side of the rib cage. The sternum is then pushed forward and stabilized by the metal bar (Fig. 83-10). With this procedure, the costal cartilage is not resected. The bar is generally left in place for 2 to 4 years, resulting in permanent chest wall remodeling. Selected adults more than 30 years old can also undergo the minimally invasive procedure.[73] Complications of this approach include bar displacement or rotation that would require reoperation, as well as pneumothorax, pericarditis, and infection. The use of thoracoscopic techniques has minimized associated complications. Overall, the rate of complications does not differ significantly between the two surgical approaches.[74] Deformity repair with either procedure impacts positively on the psychosocial well-being of the individual.[74]

Improvements in cardiopulmonary function with invasive or minimally invasive procedures remain controversial.[61] If there is improvement, it is mostly modest and clinically insignificant. Improvements in exercise tolerance, cardiac output, and VO_{2max}

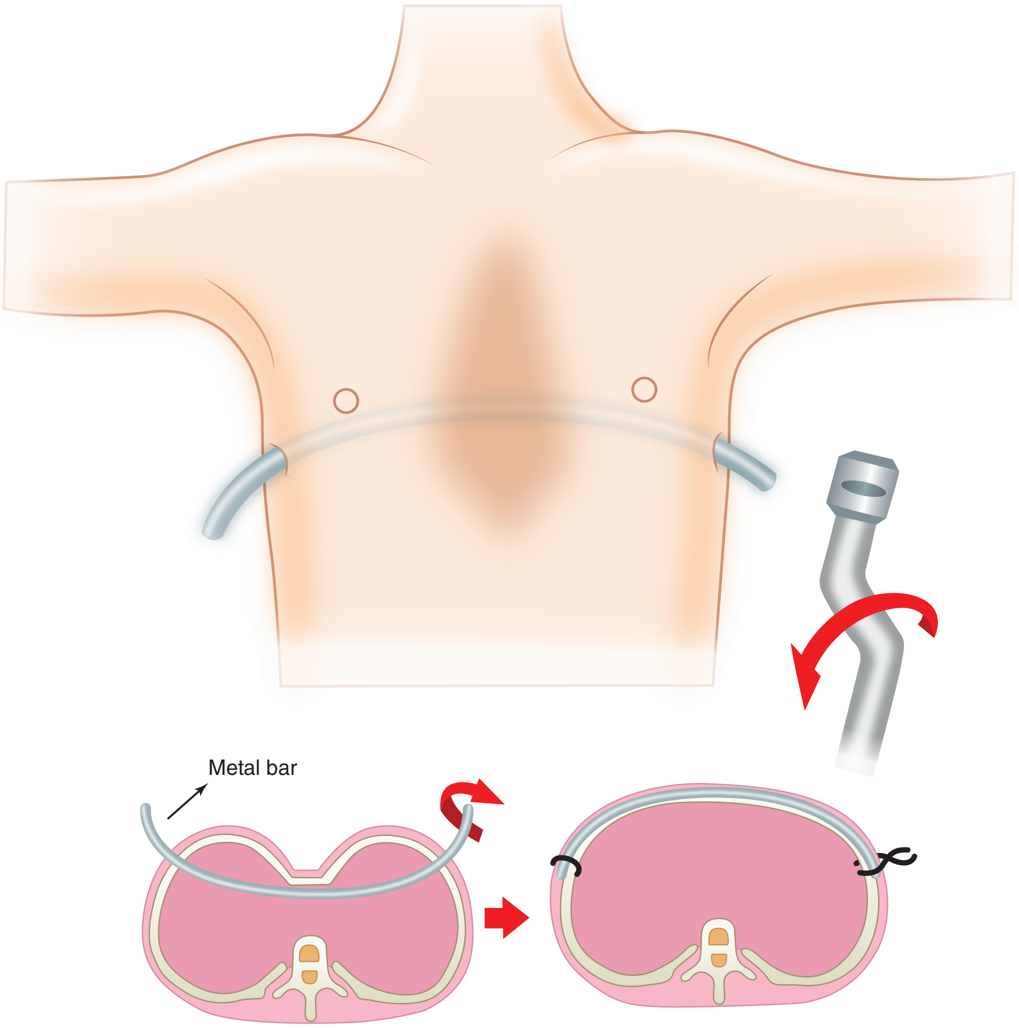

Figure 83-10 Schematic depicting the Nuss procedure in a patient with pectus excavatum. A curved bar is inserted behind the sternum and then rotated to displace the depressed sternum ventrally.

after surgical correction have been described in some but not all studies.[75,76] Discrepancies among studies may be due to differences in patient populations (younger versus older patients), surgical techniques, the interval at which tests are performed following the operation, or the effects of growth on pulmonary function. One year following surgery, any improvement in pulmonary function is independent of which surgical procedure was performed.

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis (AS) is a chronic multisystem disease characterized by inflammation of the spine and sacroiliac and peripheral joints as well as involvement of extra-articular organs including the lungs and the heart.[77] The chronic inflammation of the spinal structures and costovertebral, apophyseal, and sacroiliac joints leads to fibrosis and ossification of these structures and bony ankylosis of the costovertebral and sternoclavicular joints.[78] Consequently, spinal mobility is reduced and rib cage expansion is considerably limited.[79]

■ Etiology and Clinical Features

AS affects roughly 0.1% of the general population and is more common in men than in women, with a ratio of 16:1. Its etiology is unclear. There is a genetic predisposition for AS, as 95% of whites with AS have the HLA-B27 antigen.[80,81]

Clinically, patients in late adolescence or early adulthood present with back pain, morning stiffness due to progressive spinal rigidity, or inflammation of peripheral joints. Extra-articular manifestations such as nongranulomatous uveitis, aortitis, and dilatation of the aortic root also may occur. Onset of symptoms after the age of 45 is rare. Typically, the symptoms are worse in the morning or after prolonged rest.

Chest pain due to inflammation of manubriosternal junction and/or the sternoclavicular joints with inability to fully expand the chest on inspiration can occasionally occur (Fig. 83-11).[82] On physical exam, there may be tenderness of the anterior chest wall, the costochondral region, or the manubriosternal junction. Chronic back pain may cause sleep fragmentation resulting in difficulties with daytime somnolence and fatigue.[83] Upper airway obstruction due to cricoarytenoid cartilage involvement is a rare complication.[84]

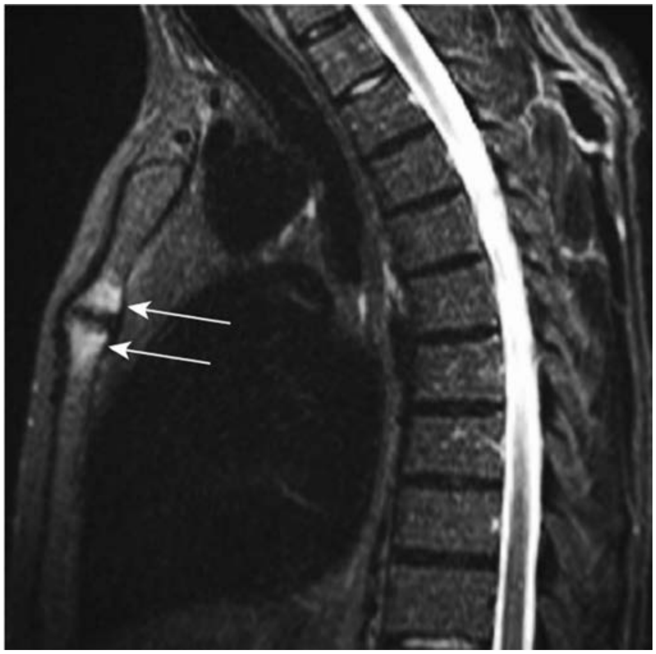

Figure 83-11 Inflammatory lesions of the anterior chest wall displayed by whole-body MRI in an ankylosing spondylitis patient complaining of anterior chest wall pain. Arrows point to bone marrow edema in both parts of the manubriosternal joint. *(Modified with permission from Weber U, Lambert RGW, Rufibach K et al. Anterior chest wall inflammation by whole-body magnetic resonance imaging in patients with spondyloarthritis: lack of association between clinical and imaging findings in a cross-sectional study. Arthritis Res Ther. 2012;14(1):R3.)*

Individuals with advanced AS have reduced rib cage motion and are more dependent on diaphragmatic breathing. Prominent abdominal excursion during inspiration may be apparent in supine or upright individuals. The degree of rib cage immobility can be assessed by measuring the change in rib cage circumference at the level of the fourth intercostal space between a full inspiration and full expiration. Rib cage expansion less than 3 cm should raise the possibility of AS in young patients with chronic low back pain.[85]

■ Respiratory Pathophysiology

Limited rib cage expansion is the pathophysiologic hallmark of AS.[78] This limitation results from fusion of the costovertebral and sternoclavicular joints and possibly leads to intercostal muscle atrophy.[78] Rib cage motion is similar to that in healthy individuals in terms of direction, but the magnitude of motion is severely limited.[31] Rib cage stiffness leads to a reduction in chest wall and total respiratory system compliance, but lung compliance remains normal except in cases of coexisting lung fibrosis (Table 83-4).[86] Since rib cage expansion is severely limited in advanced AS, chest wall inflation is primarily accomplished through diaphragmatic displacement of the abdomen, that is, the lung expands along the "path" of least resistance (Fig. 83-12). This pathway accounts for most of the tidal volume change during quiet breathing, speech, or exercise.[79,86,87] In this setting, the increased diaphragm shortening and the relatively greater transdiaphragmatic pressure required to inflate a stiff rib cage[78] may potentially provide a training stimulus to the diaphragm.

Only mild reductions in VC or TLC (75%–80% of predicted) may be present despite moderately severe reductions in rib cage mobility (Table 83-3).[85,88] The mild restrictive impairment is usually proportional to disease activity and duration, and to the degree of spinal and rib cage mobility.[88] The restrictive defect may increase in advanced disease when kyphosis supervenes.[89] Mild reductions of respiratory muscle strength (PI_{max} and PE_{max}) may be recorded in individuals with severely limited rib cage expansion.[88] However, diaphragmatic strength is typically intact in these patients.[78]

In the absence of parenchymal lung disease, Pa_{O_2} is either in the normal range or mildly reduced.[88] Exercise capacity may be mildly

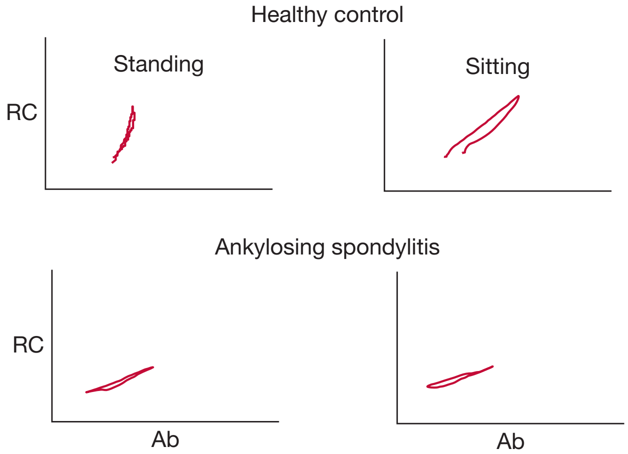

Figure 83-12 Changes in anteroposterior dimensions of the rib cage (RC) and abdomen (Ab) in a healthy individual and one with ankylosing spondylitis (AS). There is limited mobility of the rib cage in all positions resulting in greater motion of the abdomen relative to the rib cage.

decreased in patients with AS, especially in those with marked rib cage restriction.[90] The mechanism of limited exercise is most likely related to peripheral deconditioning rather than ventilatory constraints.[90]

■ Pleuropulmonary Abnormalities

Upper lobe fibrobullous disease occurs in a small percentage (up to 4%) of individuals with AS.[91] It is more common in males with long-standing disease and may manifest as interstitial infiltrates, fibrosis with honeycombing, or cavitation that may mimic tuberculosis.[91] The pathogenesis of upper lobe fibrobullous disease is unknown. Possible mechanisms include diminished upper lobe ventilation, apical mechanical stress due to rib cage rigidity, and recurrent lung infection due to impaired cough. These patients usually do not have symptoms but are at risk for spontaneous pneumothorax and infections with *Aspergillus* or atypical mycobacteria.[91] Fibrobullous disease tends to be progressive and its course is not altered by steroid treatment. Because resection of the lung segment with fibrobullous disease can be complicated by bronchopleural fistula in 50% to 60% of patients, surgery is reserved for treatment of massive hemoptysis.[91] Additional pleuropulmonary abnormalities that can be detected by chest CT in about 10% to 20% of AS patients include interstitial lung disease, pleural thickening, parenchymal bands, and bronchial wall thickening.[92] These abnormalities are subtle and do not correlate with clinical or functional impairment.

■ Sleep-Disordered Breathing

An increased prevalence of obstructive sleep apnea may occur in AS, especially in patients with long-standing disease (>5 years).[93] Because fatigue is a common complaint in AS, clinicians should have a high index of suspicion for concomitant sleep-disordered breathing contributing to excessive daytime sleepiness and screen these patients with polysomnography.[93]

■ Treatment

Treatment of individuals with AS should include pain relief, physical therapy, and measures to maintain posture and spinal flexibility and reduce complications.[80] Physical therapy exercises that promote rib cage expansion have beneficial effects on pain and spinal mobility.[94] Smoking or vaping should be avoided, and baseline chest radiographs and spirometry should be obtained.

Over the past two decades, the use of antagonists of tumor necrosis factor α (TNF-α) and most recently of monoclonal antibodies blocking IL-17A have had a dramatic effect on pain control, fatigue, spinal flexibility, and quality of life in AS patients.[80,95] Rib cage expansion is also improved following treatment with biologic agents.[94] The effectiveness of TNF-α blockade can be maintained for several years with continued treatment. Since anti–TNF-α agents do not prevent new bone formation in AS patients, their overall effects on the natural history of the disease await further assessment.[96] An adverse effect of the anti–TNF-α therapy is reactivation of tuberculosis. Therefore, AS patients who are candidates for anti–TNF-α therapy should be screened for latent tuberculosis and receive prophylactic treatment with isoniazid prior to starting treatment.[97] Additional rare adverse pulmonary complications of anti–TNF-α blockade include interstitial lung disease and development of a sarcoid-like disorder.[97,98]

OBESITY

Obesity has become a serious health problem worldwide, with its prevalence nearly tripling over the last five decades.[99] In the United States, by most recent estimates the age-adjusted prevalence of obesity in adults was 42.4%, with no significant differences between men and women, and with the prevalence of both obesity and severe obesity in adults increasing over the last two decades.[100] The trend of increasing prevalence is predicted to continue during the next decade.[101] Childhood obesity also is rising in the United States, with the latest figures showing nearly 1 in 5 children being obese.[102] The World Health Organization (WHO) has declared obesity one of the top ten risk conditions worldwide and one of the top five in developed countries. According to WHO, globally there are more people who are obese than underweight and that overweight and obesity are linked to more deaths worldwide than underweight. Obesity is associated directly or indirectly with several comorbidities, increased disability, and decreased life expectancy.[103] It is a significant contributor to escalating health care costs.[103]

TABLE 83-5 **Diagnostic Criteria for Obesity Hypoventilation Syndrome**

BMI >30 km/m^2
Daytime Pa_{CO_2} >45 mm Hg
Rise in Pa_{CO_2} of >5 mm Hg during sleep
Sleep disordered breathing
Absence of other known causes of hypoventilation

Severity of obesity is commonly assessed by calculating the body mass index (BMI), defined as body weight (BW) in kilograms divided by the square of height (Ht) in meters (BW/Ht^2). An individual with a BMI between 18.5 and 24.9 kg/m^2 is normal; a BMI between 25 and 29.9 kg/m^2 is overweight, and a BMI greater than 30 kg/m^2 is considered obese; BMI greater than 40 kg/m^2 is considered class III or severe (morbid) obesity.[104] Morbidity and premature mortality usually begin to increase at a BMI of 25 to 29.9 kg/m^2 and further increase with a BMI greater than 30 kg/m^2.

■ Clinical Features

Obesity-associated respiratory morbidity results primarily from derangements in respiratory mechanics and the control of breathing.[105] Obesity may decrease lung volumes, decrease respiratory muscle strength, increase the work of breathing, and reduce respiratory drive.[106,107] Despite these limitations, most morbidly obese patients remain eucapnic—referred to as simple obesity (SO). However, a subgroup of morbidly obese individuals develops hypercapnia.[108] These individuals have obesity hypoventilation syndrome (OHS) (Table 83-5).

■ Pulmonary Function and Chest Wall Mechanics

In SO, the most common impairments in pulmonary function include a decrease in expiratory reserve volume (ERV) and FRC.[109] In contrast, TLC is normal or only mildly reduced (Table 83-6). The lower than normal FRC is due to the increased volume of abdominal and thoracic fat that makes pleural pressure less subatmospheric.[110,111] Both factors lower resting end-expiratory relaxation volume (FRC). Residual volume (RV) may be normal or even slightly increased in SO.[109] As a result, ERV—which is the difference between FRC and RV—is reduced.[109] Expiratory flow rates and the FEV_1/FVC ratio are usually normal in SO except for modest reductions in forced vital capacity (FVC) when the BMI exceeds 45 kg/m^2.

In OHS, FRC and ERV are more severely reduced than they are in individuals with SO and a comparable BMI (Table 83-6). In OHS, TLC is reduced but to a lesser extent than FRC and ERV.[105] With BMI >60kg/m^2, up to 75% of these individuals, especially men, have diminished TLC.[106] These differences in pulmonary function between SO and OHS may be explained by differences in the distribution of adipose tissue. Individuals with OHS typically

PaO$_2$ (mm Hg)	90	83	58
PaCO$_2$ (mm Hg)	37	38	55
CRS (L/cm H$_2$O)	0.11	0.05	0.06
RRS (cm H$_2$O • L^{-1} • sec)	1.2	4.0	7.8
PImax (cm H$_2$O)	100	95	60
Work (J/L)	0.43	0.74	1.64

BW, body weight; BMI, body mass index; FVC, forced vital capacity; FEV$_1$, forced expiratory volume in 1 s; FRC, functional residual capacity; ERV, expiratory reserve volume; TLC, total lung capacity; MVV, maximum voluntary ventilation; CRS, compliance of respiratory system; RRS, resistance of respiratory system; PI$_{max}$, maximum inspiratory pressure.

have a central pattern of fat distribution. For a given BMI, a central pattern of fat distribution (measured as the waist:hip circumference ratio) is associated with greater impairment in lung function than a peripheral (around the hips) fat distribution.[112] This pattern is seen more commonly in men than in women.[113]

Respiratory system compliance is invariably decreased in obese individuals.[111,114,115] In morbidly obese patients, respiratory system compliance decreases exponentially as BMI increases. The reduction in respiratory system compliance can be primarily attributed to a decrease in lung compliance.[111] When FRC is reduced with obesity, lung compliance decreases due to airway closure and development of atelectasis. Whether a stiffened chest wall contributes to the reduction in respiratory system compliance remains controversial. Differences among studies reporting either normal or reduced chest wall compliance may be due to difficulties measuring chest wall compliance when the respiratory muscles are not fully relaxed.[111,116,117] To circumvent this issue, chest wall compliance has been measured in anesthetized, paralyzed obese individuals and found to be normal.[111,115] In this setting, the chest wall pressure-volume curve has the same slope as a nonobese individual but is shifted rightward. This rightward shift is consistent with mass loading of the thorax. Mechanistically, the excess chest wall adipose represents an inspiratory threshold load. Once the threshold load is overcome, the chest wall inflates similar to the normal chest wall.[111]

Morbidly obese individuals may have increased airway resistance,[118] exhibit expiratory flow limitation,[119] and develop intrinsic positive end-expiratory pressure (PEEP).[119] Since airway resistance remains elevated when correcting for lung volume (i.e., specific airway conductance is reduced to 50% to 70% of normal), additional factors must be contributing to increased airway resistance.[118,120] Expiratory flow limitation has been described in obese individuals during tidal breathing, especially in the supine position.[119] Flow limitation may be primarily related to shifting FRC to a region on the flow-volume curve where tidal breathing encroaches on the maximal flow-volume envelope. In the supine position, further reductions in FRC[118] increase the likelihood that expiration will be flow-limited. Intrinsic PEEP develops as a consequence of expiratory flow limitation especially in circumstances where expiratory time is reduced or tidal volume increased (i.e., exercise). Intrinsic PEEP may also develop in the supine position when FRC is further reduced. Consequently, obese individuals may complain of orthopnea.[119]

Respiratory muscle strength, as measured by PI$_{max}$ and PE$_{max}$, as well as respiratory muscle endurance, as measured by MVV, are generally preserved in SO.[121] In contrast, individuals with OHS often have a reduction in MVV and exhibit respiratory muscle weakness, with strength diminished to approximately 40% of predicted.[105,121] Mechanisms that potentially explain respiratory muscle weakness in OHS include respiratory acidosis and mechanical disadvantage of the diaphragm related to its rostral displacement by adipose tissue.[105,121]

■ Control of Breathing

Differences in the control of breathing may underlie the development of hypercapnia in some but not all obese individuals with similar BMI. In eucapnic obese individuals, the central respiratory drive (as measured by P0.1 or ventilatory or EMG responses to hypercapnia or hypoxia) is normal or increased due to excessive elastic or threshold loads imposed on the inspiratory muscles.[122–124] Specifically in the eucapnic morbidly obese, added elastic and threshold loads increase respiratory drive by 2 to 3 times that of the nonobese subject;[123] transitioning from the sitting to supine position increases further the respiratory drive in obese but not in nonobese individuals.[122] Overall, the augmented respiratory drive is strongly associated with BMI,[122] is decreased following weight loss,[125] and is important for maintaining normocapnia in obesity.[122]

Patients with OHS generally do not exhibit increased respiratory drive in response to loads placed on the respiratory muscles, and the P0.1 or ventilatory or EMG response to hypoxia or hypercapnia is diminished.[126] The mechanism accounting for the diminished ventilatory drive in OHS is unknown. Genetic tendency or respiratory mechanical disadvantage do not seem to explain it, as the ventilatory drive is intact in first-degree relatives[127] and most patients with hypercapnia can normalize Pa$_{CO_2}$ through voluntary increase in ventilation.[128] Factors that may attenuate chemosensitivity in OHS include the presence of sleep apnea, chronic hypoxia or hypercapnia, or reduced leptin or leptin resistance.[105] Leptin, a hormone produced by adipose tissue, acts in the hypothalamus to regulate appetite, food intake, and weight and also to stimulate breathing, through both central and peripheral receptors.[129–132] High serum levels of leptin are associated with reduced respiratory drive in severely obese individuals.[133] Therefore, the development of leptin resistance or relative leptin deficiency may contribute to reduced ventilatory drive and hypercapnia in OHS (Fig. 83-13).[133]

Basal O$_2$ consumption and CO$_2$ production are increased in morbid obesity.[116] Because of these increased demands, morbidly obese individuals require higher levels of alveolar ventilation to maintain eucapnia and thus have an increased work of breathing.[117] To attain the requisite levels of ventilation and minimize the work per breath, obese individuals adopt a rapid shallow breathing pattern with breathing frequency about 40% higher than that of nonobese individuals.[124] The increase in breathing frequency is accomplished by shortening both inspiratory and expiratory time while the ratio of inspiration to total breath time (T_I/T_{TOT}) remains normal.[124,134] A rapid shallow breathing pattern allows them to minimize the elastic and resistive work per breath. This pattern is amplified in OHS.[123,134] These individuals have a breathing frequency that is higher and a tidal volume that is about 25% lower than individuals with SO.[123,134]

Exercise capacity is near normal in SO.[135] During treadmill exercise, minute ventilation, respiratory rate, heart rate, and oxygen

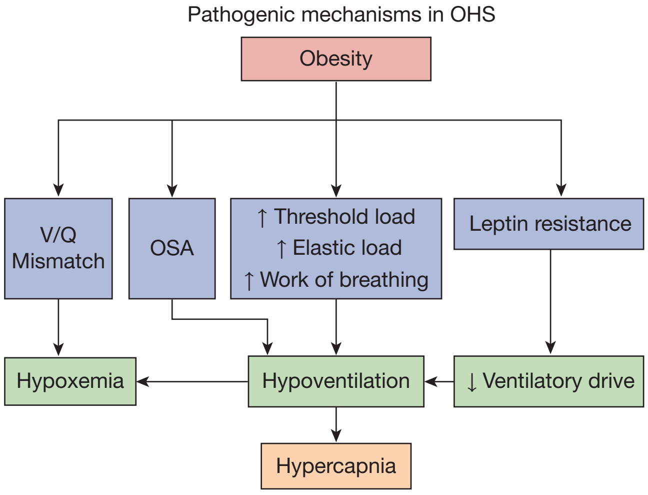

Figure 83-13 Factors involved in the pathophysiology of obesity hypoventilation syndrome. OSA, obstructive sleep apnea.

consumption are generally higher in obese individuals than in normal-weight individuals.[135] However, the anaerobic threshold is lower than in normal-weight individuals.[135] With weight loss, the metabolic demands are reduced and carbon dioxide production and alveolar ventilation are reduced by approximately 20%.[136]

Gas Exchange

Hypoxemia is either mild or absent in SO, whereas it is usually present in OHS.[137] Hypercapnia during wakefulness, the defining characteristic of OHS, rarely occurs in overweight individuals with BMI less than 30 kg/m^2.[137] In obese individuals with BMI greater than 30 kg/m^2, Pa_{O_2} is negatively and Pa_{CO_2} positively related with BMI (Fig. 83-14).[137] In OHS, gas exchange abnormalities are due primarily to hypoventilation. The presence of ventilation-perfusion mismatch at the lung bases widens the alveolar-arterial oxygen gradient and worsens hypoxemia.[138] Gas exchange abnormalities are amplified when obese individuals assume the supine position. This can be a major concern during induction of anesthesia, as these individuals may become profoundly hypoxemic.[139]

Treatment

Although difficult, dietary changes combined with exercise and behavioral modifications can lead to weight loss in some obese individuals. However, these modalities are usually not successful in maintaining long-term weight loss.[140] Bariatric surgery has evolved into a relatively common intervention that can produce not only weight loss but also long-term maintenance of weight loss.[141] In patients with OHS and acute or chronic hypercapnic respiratory failure, the use of positive airway pressure devices with sleep may improve gas exchange, daytime somnolence, and quality of life.[108,142,143]

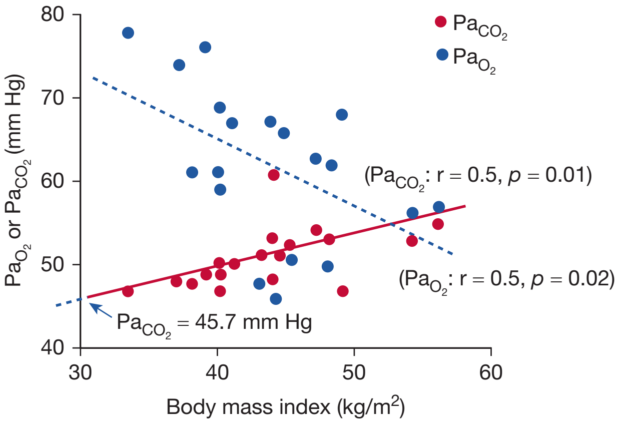

Figure 83-14 Relationship between Pa_{CO_2} and Pa_{O_2} with body mass index in patients with obesity hypoventilation syndrome. *(Reproduced with permission from Mokhlesi B. Obesity Hypoventilation Syndrome: A State-of-the-Art Review. Respir Care. 2010;55(10):1347–1362.)*

Weight loss, induced either by diet or surgical intervention, has beneficial effects on pulmonary function, gas exchange, and ventilatory control in both OS and OHS.[105,144] A weight loss of about 40 kg leads to a significant increase in ERV and, to a lesser extent, increases in FRC, VC, and TLC.[105] However, there is no correlation between the magnitude of weight loss and the degree of improvement of lung volumes. The Pa_{O_2} increases by about 4 to 8 mm Hg due to improved ventilation of the lung bases; additionally, CT may show clearing of air trapping.[145] In OHS, the effects of weight loss on ERV and FRC are more pronounced than in SO, with VC increasing as well.[146] Additional benefits of weight loss include improvements of respiratory muscle performance,[147] dyspnea scores,[144] sleep apnea,[148] 6-min walk test,[149] airway responsiveness,[150] and respiratory drive.[125] Overall, the effective and sustained weight loss that may follow bariatric surgery appears to be the best option for ameliorating the various comorbid conditions related to obesity such as hypertension, hyperlipidemia, or type 2 diabetes.[151]

FLAIL CHEST

Flail chest refers to a condition in which multiple rib fractures produce a segment of the rib cage that deforms noticeably during breathing. According to a classic definition, double fractures of three or more adjacent ribs or the combination of sternal and rib fractures are required to produce a flail segment of the rib cage and lead to respiratory failure.[31] The flail segment is displaced inwards rather that outward during inspiration. By contrast, the term "non-integrated chest wall" denotes a similarly unstable segment of the chest wall resulting from multiple single rib fractures in a single plane and causing respiratory failure.[152]

Etiology and Diagnosis

Flail chest can occur in up to 15% of adults with chest wall trauma.[153] The most common cause of flail chest is trauma related to automobile accidents or falls.[154] Other causes include rib fractures after aggressive cardiopulmonary resuscitation and rarely pathologic rib fractures (i.e., multiple myeloma, other metastases).

The diagnosis of flail chest can readily be made in spontaneously breathing individuals by observing the paradoxical motion of the flail segment of the rib cage. In fully sedated mechanically ventilated patients the diagnosis may be delayed until patients resume spontaneous breathing.[155] Chest radiographs showing multiple rib fractures confirm the diagnosis but usually miss 50% of rib fractures, especially those at the costochondral junction.[156] Chest CT with reconstruction of the rib cage is the best imaging modality to visualize rib fractures and to demonstrate the extent of injuries to the pleura and pulmonary parenchyma (Fig. 83-15).[157]

The mortality of chest wall trauma with no flail present ranges between 7% and 14%. When chest wall trauma is complicated by flail chest, the mortality rate further increases.[152,158] This can be attributed to pulmonary complications such as pulmonary contusion, hemothorax, or pneumothorax, which can occur in up to 60% of patients with flail chest.[158] In addition, trauma sufficient to cause flail chest is often accompanied by extrathoracic injuries such as head trauma, rupture of the aortic arch or other arteries, laceration of the spleen or liver, and fractures of the long bones, all of which increase morbidity and mortality.[158] Patients with multiple

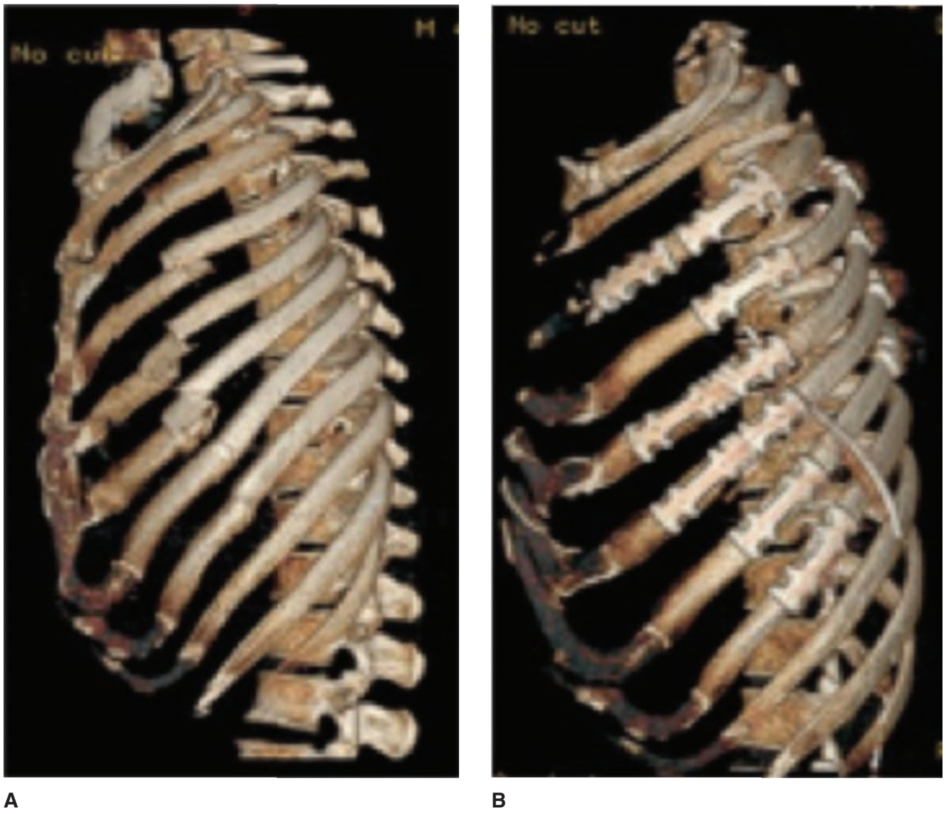

Figure 83-15 Reconstructed three-dimensional computed tomographic scan depicting a flail chest before (**A**) and after (**B**) repair with osteosynthesis plates to enable chest wall fixation. *(Reproduced with permission from Zhang X, Guo Z, Zhao C, et al. Management of patients with flail chest by surgical fixation using claw-type titanium plate. J Cardiothorac Surg. 2015;10:145.)*

trauma and lung contusion complicating flail chest have mortality as great as 56%. Age greater than 65 years is strongly associated with increased mortality in patients with flail chest.[159] In survivors of flail chest, long-term disability consisting of chest tightness, chest pain, or exertional dyspnea may occur.[160]

■ Respiratory Function and Respiratory Mechanics

Disruption of the rib cage integrity in flail chest seriously alters the function of the chest wall. Normally, rib cage expansion is accomplished primarily through the coordinated contraction of the diaphragm and the intercostal muscles and through an increase in intra-abdominal pressure in the zone of apposition of the diaphragm to the rib cage. At low lung volumes, the outward acting elastic recoil of the chest wall also assists rib cage expansion. During inspiration, pleural pressure becomes subatmospheric, which is inflationary to the lung and deflationary to the rib cage. With flail chest, a segment of the chest wall is uncoupled from the forces that promote rib cage expansion, therefore making the flail segment responsive to intrapleural pressure changes (Fig. 83-16).[161] Consequently, the flail segment moves inwards rather than outwards during inspiration. During expiration, pleural pressure becomes more positive, and the flail segment moves outward. When the normal swings in pleural pressure are augmented by reduction in lung compliance (pulmonary contusion, or atelectasis) or increase in airway resistance (bronchial secretions, or bronchospasm), there is greater paradoxical motion of the flail segment.[161]

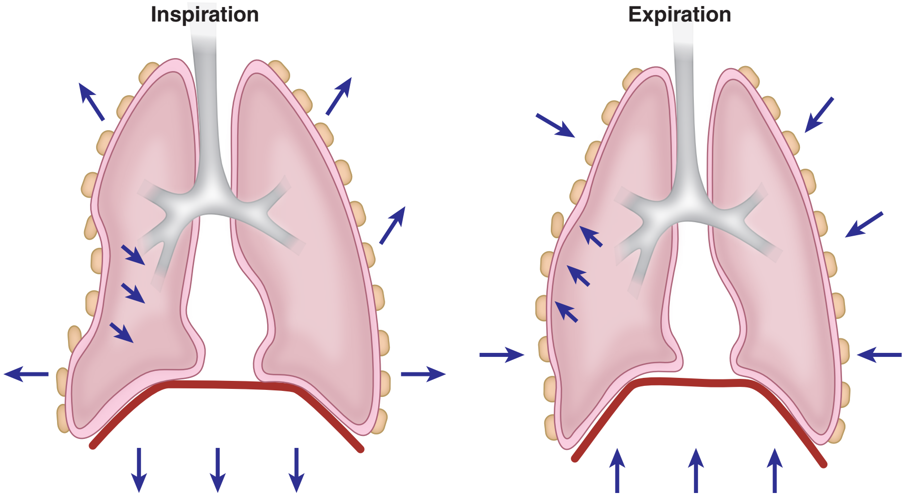

Figure 83-16 During inspiration, pleural pressure becomes more negative causing the flail segment to move paradoxically inward as the remainder of the chest wall is moving outward. During expiration, pleural pressure increases, causing the flail segment to move outward as the remainder of the chest wall becomes smaller.

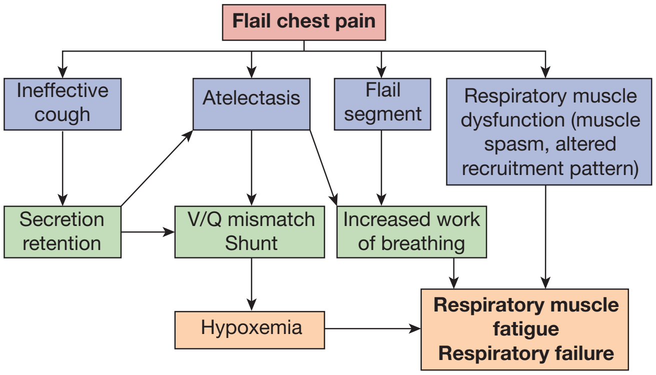
The most common anatomic location for flail chest is the lateral rib cage. Anterior flail chest occurs when there are separations between the sternum and the ribs.[158] Posterior flail chest is associated with less severe clinical derangements due to splinting provided by the paravertebral muscles. The pattern of paradoxical rib cage and abdominal motion is not unique to the location of the flail segment. Paradoxical chest wall motion may occur within the rib cage itself (i.e., between the upper and lower rib cage), or between the rib cage and abdomen (i.e., lower rib cage and anterior abdominal wall).[161] These different patterns of motion of flail chest may reflect different respiratory muscle recruitment patterns.[161] Supporting evidence for alteration in the pattern of respiratory muscle action is the observation that EMG activity of the external intercostals muscles increases more than threefold in the flail region.[162]

VC and FRC can be reduced to as much as 50% of predicted in patients with flail chest.[163] Paradoxical movement of the flail segment and coexisting pulmonary contusion contribute to reductions in VC. In patients with pulmonary contusion complicating flail chest, VC and FRC may remain reduced for up to 4 years due to fibrous changes in the contused area.[155] With surgical stabilization of the flail segment, VC usually returns to normal range in about 3 months.[164]

The pathogenesis of respiratory failure in flail chest is complex. The simplified theory of a pendelluft-like movement of gas from the normal hemithorax to the flail hemithorax is not valid. Rather, flail-induced changes in lung and respiratory muscle function likely contribute to respiratory failure. Specifically, flail chest is accompanied by considerable pain, which can impair cough effectiveness, cause regional atelectasis, induce rib cage muscle spasm, and alter the pattern of respiratory muscle activation and recruitment. In addition, flail chest may increase the elastic load imposed on the respiratory muscles through development of regional (near the flail segment) or generalized atelectasis (due to splinting and pain). Associated pulmonary contusion also would increase the elastic load and work of breathing. In addition, the work of breathing is increased because the inspiratory muscles have to shorten more for a given tidal volume. The excessive muscle shortening represents extra work that is not measured using standard calculations of work per breath. (The muscles shorten but do not produce measurable flow at the mouth.)[161] Another adverse consequence of excessive inspiratory muscle shortening is a reduction in the mean operating length of the inspiratory muscles. When the inspiratory muscles are activated at a shorter than optimal length, inspiratory muscle efficiency is reduced, thereby adding to the oxygen cost of breathing.[161] The combination of added work of breathing, respiratory muscle inefficiency, hypoxemia due to atelectasis, and pulmonary contusion all combine to predispose these patients to respiratory muscle fatigue and respiratory failure (Fig. 83-17).



Flail chest pain
Ineffective cough
Atelectasis
Flail segment
Respiratory muscle dysfunction (muscle spasm, altered recruitment pattern)
Secretion retention
V/Q mismatch Shunt
Increased work of breathing
Hypoxemia
Respiratory muscle fatigue Respiratory failure

Treatment

Early restoration of structural and functional integrity of the chest wall is crucial to preventing flail chest–related complications. Conservative and surgical methods are used to stabilize the flail segment. The basic objective of conservative treatment is to control pain and minimize atelectasis through chest physiotherapy and clearance of bronchial secretions. Pain control can be accomplished by use of oral or intravenous narcotics, intercostal nerve blocks, or epidural anesthesia.[165] Adequate pain relief in combination with supplemental oxygen, frequent tracheal bronchial toilet, and cautious fluid replacement often prevents development of respiratory failure and leads to successful treatment of flail chest.

Mechanical ventilation with positive-pressure breathing can stabilize the flail segment by eliminating the subatmospheric changes of pleural pressure that occur during spontaneous breathing. Prolonged mechanical ventilation as a means of treating flail chest was proposed in the 1960s and was initially accomplished through tracheostomy. However, complications related to mechanical ventilation, such as pneumonia and increased morbidity and mortality, led to abandoning this modality as a primary means of stabilizing the chest wall. Currently, mechanical ventilation is indicated when there is respiratory failure, concomitant central nervous system or intra-abdominal injuries, shock, or the need to operate for other injuries. If mechanical ventilation delivered via an endotracheal tube is instituted, ventilator modes that minimize patient effort and the generation of subatmospheric pleural pressure should be employed. For example, low-impedance modes of mechanical ventilation (i.e., high-flow continuous positive airway pressure) are associated with less chest wall distortion during inspiration.[161]

Noninvasive positive-pressure ventilation may provide an alternative means of stabilizing the flail segment in selected patients who are breathing spontaneously.[166,167] This modality in conjunction with regional anesthesia can improve gas exchange and enable physiotherapy and early patient mobilization. In selected patients with flail chest, noninvasive ventilation may significantly reduce morbidity and length of hospitalization.[166,167] A randomized control trial comparing patients with mask CPAP versus assist control ventilation found that patients treated with mask CPAP had fewer complications, a shorter hospital and intensive care unit length of stay, and less ventilator time than patients with similar degrees of blunt thoracic trauma treated with assist control ventilation.[166] Although larger trials evaluating noninvasive positive-pressure ventilation in flail chest are needed for further validation, this modality may be useful when pain is controlled and hypoxemia is not severe.[168]

Surgical fixation of the flail chest has received increased attention over the last two decades, as it can potentially provide substantial benefits to mechanically ventilated patients. In selected patients with flail chest, fixation of the chest wall with wires, steel plates, and splints improves respiratory mechanics and reduces the duration of mechanical ventilation as well as hospital stay (Fig. 83-15).[169–172] Operative fixation will likely benefit patients who are ventilator dependent and able to protect their upper airways. Other potential candidates may be patients undergoing thoracotomy for intrathoracic injuries, young patients with severe chest deformation, or patients with large unstable segments and borderline pulmonary function. The indications for operative fixation remain controversial largely due to the lack of studies comparing operative and nonoperative treatment.[173]

CHAPTER 84

Effects of Neuromuscular Diseases on Ventilation

Gerard Joseph Criner
Nathaniel Marchetti

INTRODUCTION

Neuromuscular diseases are a diverse group of disorders that vary markedly in etiology, rate of progression, pattern of respiratory involvement, prognosis, and therapy. Neuromuscular disorders impair the respiratory system as a vital pump; however, depending on the particular disease, the respiratory pump may be impaired at the level of the central nervous system (e.g., cerebral cortex or brain stem), spinal cord, peripheral nerve, neuromuscular junction, or respiratory muscle (Table 84-1).

The pattern of ventilatory impairment among these disorders is highly dependent on the specific neuromuscular disease. For example, some disorders may impair ventilation at only one level (e.g., isolated diaphragm paralysis) or simultaneously affect it at different levels (e.g., multiple sclerosis). Additionally, the severity of impairment may be minimal and totally resolve with time and proper treatment (e.g., Guillain-Barré syndrome) or is characterized by relentless progression to eventual respiratory death (e.g., amyotrophic lateral sclerosis). Moreover, some neuromuscular diseases concomitantly affect several structures (e.g., swallowing dysfunction in poliomyelitis, interstitial lung disease in polymyositis), increasing ventilatory workload in patients who already have diminished ventilatory reserve.

In this chapter we describe the etiology, pathophysiology, and treatment of ventilatory dysfunction in neuromuscular diseases.

RESPIRATORY PATHOPHYSIOLOGY

Substantial information exists concerning the ventilatory function of patients with neuromuscular disease at rest and during sleep, as well as the effects on maximum static inspiratory and expiratory efforts and responses associated with these disorders to hypoxic and hypercapnic challenges. In general, the response of the respiratory system to moderate or severe neuromuscular disease is relatively stereotyped. The typical features are a reduced forced vital capacity, reduced respiratory muscle strength, and, in some cases, malfunction of the neurons that control breathing.

Control of Breathing

The breathing pattern is often abnormal in patients with neuromuscular disease. In comparison with healthy subjects, patients with respiratory muscle weakness have a low tidal volume and a high respiratory rate that persists in response even to hypoxic or hypercapnic challenge. Moreover, this rapid, shallow breathing pattern is not due to abnormalities in gas exchange (i.e., hypoxemia or hypercapnia) but is more likely to be due to severe muscle weakness and/or disordered afferent and efferent output in motor neurons impaired by the underlying neuromuscular disease.[1]

Changes in ventilation can be used to evaluate ventilatory drive in subjects with normal lung and respiratory muscle mechanics. However, ventilation is not a good index of respiratory motor activity in subjects with significant respiratory muscle weakness because the thoracic bellows cannot perform increased work of breathing. Decreased ventilatory response to hypoxic or hypercapnic challenge in these patients could indicate abnormalities in afferent information from diseased respiratory muscles, abnormal lung or chest wall mechanics, or upper motor neuron dysfunction, rather than an abnormality in the central control of breathing. In some neuromuscular diseases, degenerative changes in the muscle spindle, impaired afferent stimulation from abnormal stretch reflexes in the muscle spindles, or decreased mechanoreceptor output from tendons may explain the altered breathing pattern.[1]

Measurement of mouth occlusion pressure generated during the first 100 ms of inspiration ($P_{0.1}$) is relatively independent of inspiratory effort and therefore is a more reliable estimate of central ventilatory drive independent of respiratory muscle mechanics.[2] $P_{0.1}$ is maintained or increased in patients with neuromuscular disease despite substantial muscle weakness. The relationship between respiratory mechanics, respiratory muscle strength, and control of ventilation has been examined in patients with neuromuscular diseases in comparison with healthy control subjects. Although

TABLE 84-1 Levels of Respiratory System Dysfunction Induced by Neuromuscular Diseases and Conditions

Level	Disease or Condition
Upper motor neuron	Parkinson disease
Cerebral	Vascular accidents Cerebellar atrophy Trauma
Spinal cord	Trauma Tumor Syringomyelia Multiple sclerosis
Lower motor neuron	
Anterior horn cells	Poliomyelitis Spinal muscle atrophy Amyotrophic lateral sclerosis
Motor nerves	Cardiac surgery Charcot–Marie–Tooth disease Diabetes Polyneuropathy Toxins Guillain–Barré syndrome
Neuromuscular junction	Neuralgia amyotrophy Critical illness polyneuropathy Myasthenia gravis Eaton–Lambert syndrome
Muscle	Botulism Organophosphate poisoning Drugs Dystrophy Acid maltase deficiency Malnutrition Corticosteroids Polymyositis

patients had 37% and 52% reductions in maximum inspiratory and expiratory mouth pressures, respectively, their $P_{0.1}$ was 66% greater than that of controls.[1]

Similar findings were encountered when normal subjects had acute muscle weakness induced by curarization. After severe muscle weakness was induced, significant increases in $P_{0.1}$ were observed during hypercapnic challenge.[3] Partial curarization of spontaneously breathing cats also produced a marked increase in phrenic nerve discharge despite a substantial decrease in minute ventilation.[4] These studies indicate that under conditions of substantial respiratory muscle weakness, ventilation is not a reliable measure of central respiratory drive, and that central respiratory drive, at least when measured by $P_{0.1}$, is usually well preserved.

■ Respiratory Muscle Function

Patients with neuromuscular disease who develop significant respiratory muscle weakness may experience fatigue, dyspnea, and impaired control of secretions, recurrent lower respiratory tract infections, acute or chronic presentations of respiratory failure, pulmonary hypertension, and cor pulmonale.

The pattern, prognosis, and degree of respiratory muscle weakness attributable to a neuromuscular disorder are varied. They depend on the level of neuromuscular system impairment, the prognosis of the underlying disorder, and whether therapy is available. Patients with neuropathy, such as in Guillain-Barré syndrome, tend to have less severe respiratory muscle weakness than patients with lower motor neuron lesions or neuromuscular junction disorders, such as myasthenia gravis. Even when respiratory muscle dysfunction is observed, not all respiratory muscles are equally impaired, and the course of the underlying neuromuscular disease and degree of respiratory and nonrespiratory muscle impairment can be very different between patients with the same disease. In some neuromuscular disorders, respiratory muscle weakness is the only presentation of an underlying disease (i.e., neuralgia amyotrophy of the diaphragm); in the case of muscular dystrophy, significant respiratory muscle weakness may occur only late in the disease course. Severe, relentless, progressive dysfunction of the respiratory muscles may occur, as in amyotrophic lateral sclerosis, or be characterized by exacerbations and relapses (e.g., multiple sclerosis). Finally, respiratory muscle weakness may completely reverse with time (phrenic nerve injury after open-heart surgery) or with therapy (plasmapheresis in myasthenia gravis).

A significant proportion of patients with severe respiratory muscle weakness were also found in 50% of 30 asymptomatic patients with stable chronic neuromuscular disease. Reductions in inspiratory and expiratory mouth pressures did not correlate with general muscle strength assessment; however, the type of neuromuscular disease and distribution of general muscle weakness both correlated with respiratory muscle impairment.[5] Patients with myopathy, rather than polyneuropathy, whose involvement produced proximal rather than distal limb muscle weakness, were more likely to have significant respiratory muscle weakness. Pulmonary symptoms correlated poorly with evidence of respiratory muscle weakness.

Explanations for the lack of pulmonary complaints in these two studies, despite significant muscle weakness, are not clear. Patients with chronic and severe neuromuscular disease are usually sedentary and incapable of exertion and, therefore, seldom stress the respiratory system—which may explain their lack of symptoms.

The rapid, shallow breathing pattern found in patients with respiratory muscle weakness may be due to decreased respiratory muscle force generation, but it may also be due to changes in lung and chest wall elastic recoil. A decrease in inspiratory muscle tone may lead to unopposed lung elastic recoil, which reduces lung volume and produces chronic changes in chest wall tone and distensibility. Once inspiratory muscle strength decreases to approximately 30% of normal, abnormalities in gas exchange (manifested primarily by hypercapnia) commonly occur.

Expiratory muscle weakness is also commonly observed in patients with neuromuscular disease. It causes ineffectual cough and impaired secretion clearance, which in some patients leads to recurrent lower respiratory tract infections. In normal persons, dynamic compression of the central intrathoracic airways by large changes in pleural pressure generated by forceful contraction of the expiratory muscles acts to propel secretions proximally, where they can be expectorated. As expiratory muscle weakness progresses, pleural pressures generated during coughing efforts are reduced and airway clearance is impaired.

■ Lung and Chest Wall Mechanics

A characteristic hallmark of chronic neuromuscular disease is a decreased vital capacity (VC). The VC is reduced because of respiratory muscle weakness, and the decrease in VC parallels the progression of the underlying disease, but the magnitude of the reduction in VC is greater than expected solely based on the reduction in respiratory muscle force. The sigmoidal shape of the pressure–volume curve would suggest that large reductions in pressure initially produce only small reductions in lung volume. In 25 patients with a variety of neuromuscular diseases, De Troyer found that reductions in VC were much greater than expected, solely based on the reductions in inspiratory muscle strength[6] **(Fig. 84-1)**.

It appears that in addition to muscle weakness, alterations in the mechanical properties of the lung and chest wall contribute to the reduced VC. Using the mean deflationary pressure–volume curve of the lung in 25 patients with moderate to severe neuromuscular disease, De Troyer et al. found, on average, a 40% decrease in lung compliance[6] **(Fig. 84-2)**. Furthermore, measurements of static lung compliance measured during inspiration in patients with neuromuscular diseases also show marked reductions, suggesting that chronic respiratory muscle weakness changes the elastic properties of the lung itself.[7]

The cause of reduced lung distensibility in patients with neuromuscular disease is unknown. Several causes—such as failed maturation

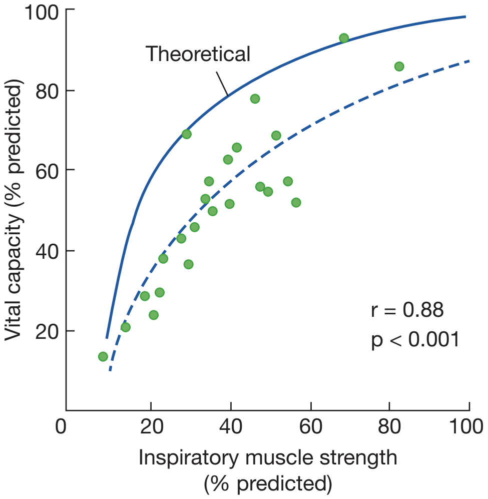

Figure 84-1 The *solid curve* represents the theoretic effect of respiratory muscle weakness on vital capacity (VC) on the assumption that the relaxation pressure–volume characteristic of the lung and chest wall are normal and that the inspiratory and expiratory muscles are uniformly involved. *Dashed curve* is the logarithmic regression calculated in 25 patients with neuromuscular disease *(closed circles)*. Data suggest that loss of lung volume is out of proportion to the degree of inspiratory muscle weakness. *(Data from De Troyer A, Borenstein S, Cordier R. Analysis of lung volume restriction in patients with respiratory muscle weakness. Thorax. 1980;35(8):603–610.)*

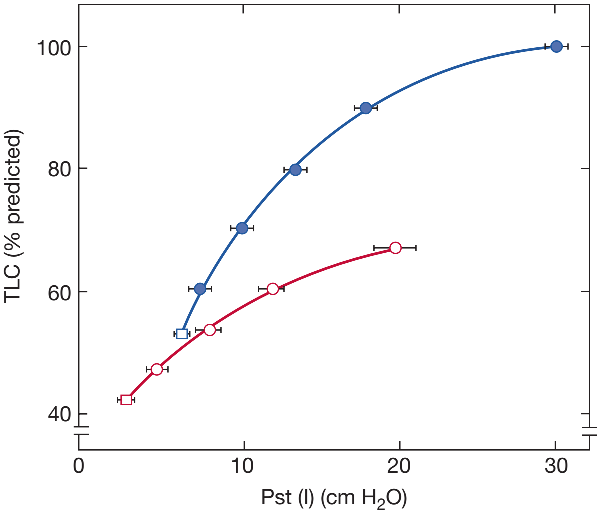

Figure 84-2 Static expiratory pressure–volume curve in patients with neuromuscular disease and respiratory muscle weakness. *Open circles* represent average data in 25 patients. Volume is displayed on the Y-axis as a percentage of predicted total lung capacity (TLC). *Closed circles* represent mean predicted values. In patients, absolute lung volume was decreased for any given transpulmonary pressure. *(Data from De Troyer A, Borenstein S, Cordier R. Analysis of lung volume restriction in patients with respiratory muscle weakness. Thorax. 1980;35(8):603–610.)*

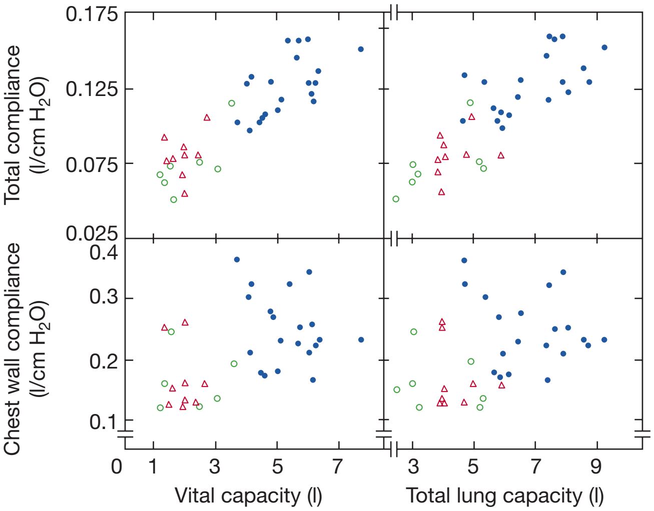

Figure 84-3 Relationships between total respiratory system compliance and VC and TLC (upper panels) and between chest wall compliance and VC and TLC (lower panels) in 16 patients with chronic neuromuscular diseases *(open symbols)* compared to 20 healthy controls *(closed circles)*. *Triangles* symbolize patients who are quadriplegic, *squares* symbolize patients who are paraplegic and four patients had generalized neuromuscular diseases *(circles)*. Compared to healthy controls *(closed circles)*, those with neuromuscular disease had significant reductions in both total respiratory system and chest wall compliance. *(Data from Estenne M, Heilporn A, Delhez L, ety al. Chest wall stiffness in patients with chronic respiratory muscle weakness. Am Rev Respir Dis. 1983;128(6):1002–1007.)*

of normal lung tissue during childhood or congenital neuromuscular diseases, the presence of micro- or macroatelectasis, increased alveolar surface tension caused by breathing chronically at low tidal volumes, and alteration in lung tissue elasticity—have been proposed.

Impaired lung maturation is unlikely, since patients who develop neuromuscular disease in adulthood also have a reduction in VC that is disproportionate to the magnitude of respiratory muscle weakness. The presence of micro- and macroatelectasis also appears untenable because most patients who have significant reductions in VC typically do not have alveolar collapse on radiographic imaging. Although rapid and shallow breathing patterns are encountered in patients with chronic severe neuromuscular disease, mechanical hyperinflation of the lung does not restore lung distensibility. Therefore, increased alveolar surface tension is not considered the principal cause of reduced lung compliance in patients with chronic neuromuscular disease.

Theoretically, a reduction in lung tissue elasticity may also contribute to a reduction in lung compliance in patients with neuromuscular disease, but there is no evidence that lung collagen, elastin, and other matrix proteins change in these diseases. Currently, the reason for the reduction in lung compliance in patients with chronic neuromuscular disease is unknown and awaits further study.

Many studies indicate that chest wall compliance is decreased by approximately 30% in patients with chronic neuromuscular disorder. In 16 patients with chronic neuromuscular diseases (e.g., spinal cord injury, Duchenne muscular dystrophy, myasthenia gravis), the weighted spirometer technique was used to examine chest wall compliance in comparison with that of 20 healthy control subjects. The weighted spirometer technique delivers an airway pressure that causes an increment in thoracic volumes so as to construct the pressure–volume relationship. In 12 of these patients, chest wall compliance was reduced[8] (Fig. 84-3). Based on the contour of the pressure–volume curve of the normal relaxed chest wall at lower lung volumes, a reduction in functional residual capacity (FRC), as seen in patients with chronic neuromuscular diseases, may, in itself, reduce static chest wall compliance. However, in other disorders in which FRC is decreased owing to parenchymal lung disease (e.g., pulmonary fibrosis), a reduction in chest wall compliance has not been demonstrated. The mechanism for the reduction in chest wall compliance in patients with chronic neuromuscular disease has not been definitely established, but limitations in respiratory excursions have been proposed to lead to increased rib cage stiffness by decreasing the viscoelasticity of chest wall structures. Regardless of the mechanism, it appears that a reduction in chest wall compliance, along with a decrease in lung compliance, contributes to the marked decrease in VC observation in patients with neuromuscular disease.

Although reductions in VC appear to be clearly established in patients with chronic neuromuscular disease, the effects of chronic neuromuscular disease on FRC and residual volume (RV) are contradictory. FRC and RV have been reported to be unchanged, decreased, or mildly increased. Discrepancies between these studies could be explained by differences in the type of severity, and stages of neuromuscular diseases studied or body positions in which testing were performed. However, in two separate studies, patients with a wide variety of chronic neuromuscular diseases, all studied in a similar seated position, were found to have approximately 20% reductions in FRC but normally predicted values of RV.[9,10] Furthermore, confirmation of these findings was demonstrated in eight patients with myasthenia gravis given pyridostigmine, which acutely decreased FRC by approximately 15% without any significant change of RV.[11] On the basis of the above data, it appears that patients with chronic neuromuscular disease have moderate reductions in VC and total lung capacity (TLC) that are associated with a moderate decrease in FRC and a normal RV. The decrease in VC not only is due to respiratory muscle weakness but also appears to result from decreased lung and chest wall compliance. Table 84-2 summarizes the effect of neuromuscular diseases on both lung volumes and central respiratory drive.

■ Sleep-Related Breathing Disturbances

Breathing during sleep is often abnormal in patients with neuromuscular disease. Impaired sleep quality and hypopnea and hypercapnia

TABLE 84-2 Characteristic Changes in Respiratory Mechanics in Patients with Neuromuscular Disease

Central drive	Rapid shallow breathing pattern
	Decreased ventilatory response to hypoxic or hypercapnic challenge
	Normal or increased $P_{0.1}$ to hypoxic or hypercapnic challenge
Lung volumes	Decreased vital capacity (VC)
	Decreased inspiratory capacity (IC)
	Decreased functional residual capacity (FRC)
	Decreased expiratory reserve volume (ERV)
	Maintained residual volume (RV)

related to rapid eye movement (REM) sleep are frequent. Patients with chronic neuromuscular disease of various causes have significant and numerous episodes of nocturnal desaturation, which are most prevalent during REM sleep and are characterized by hypoventilation rather than upper-airway obstruction[12] (Fig. 84-4). Of six patients, 16 to 22 years of age, with advanced Duchenne muscular dystrophy, randomized to breathing either air or oxygen on two consecutive nights, five demonstrated significant oxygen desaturation during REM sleep and approximately 35% reductions in minute ventilation compared with their baseline awake values. Furthermore, the severity of diaphragmatic dysfunction was related to the degree of oxygen desaturation.[13]

Several hypotheses have been proposed to explain nocturnal desaturation. Patients with chronic neuromuscular diseases develop an even more rapid and shallow breathing pattern during REM sleep. A rapid and shallow breathing pattern leads to increased dead-space ventilation, which promotes hypercapnia and worsened oxygenation. Reductions in ventilatory drive may be accentuated during sleep in patients with underlying neuromuscular disease—especially in those who have preexisting abnormalities of ventilatory control, which may further contribute to worsened nocturnal hypoventilation.

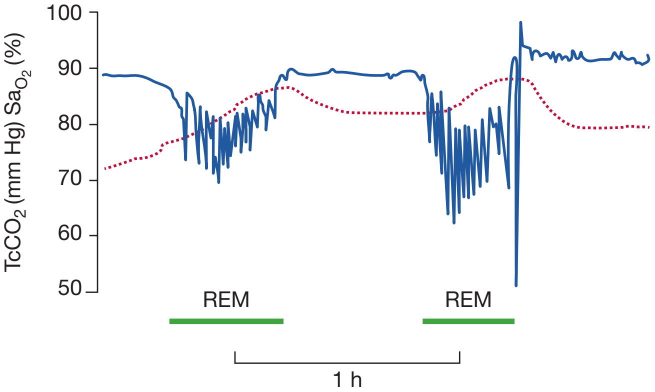

Figure 84-4 Oxygen desaturation and hypercapnia in REM sleep shown from a recording of an all-night sleep study. Transcutaneous carbon dioxide ($TcCO_2$) is shown as the *dashed line*; arterial hemoglobin oxygen saturation (Sa_{O_2}) is shown in the line with sharp deflections. Patients with neuromuscular diseases are often at risk for hypoventilation during REM sleep resulting in a decrease in Sa_{O_2} and increase in TcO_2. *(Data from Bye PT, Ellis ER, Issa FG, et al. Respiratory failure and sleep in neuromuscular disease. Thorax. 1990;45(4):241–247.)*

It has been hypothesized that patients with neuromuscular disease, especially with diaphragmatic dysfunction, may be more prone to nocturnal desaturation during REM sleep. Intercostal muscle and accessory respiratory muscle activity during REM sleep are depressed, with a greater contribution of the diaphragm required for maintenance of eucapnia and oxygenation. Support for this hypothesis comes from studies that have found diaphragm dysfunction to be highly correlated with the presence and magnitude of REM-related oxygen desaturation. A direct relation has been found between the lowest SaO_2 value measured during REM sleep and the percentage fall in VC measured between the erect and supine positions, using the latter measurements as an index of diaphragm weakness. Similarly, among patients who have paradoxical abdominal movement, signifying a decrease in diaphragmatic contribution to ventilation, a greater oxygen desaturation in both REM and non-REM sleep is observed.[14] In contrast, patients with isolated diaphragmatic dysfunction with intact accessory muscle function are not predisposed to severe nocturnal hypoventilation.[15] Accordingly, severe hypoventilation may become evident only when diaphragmatic weakness is found in the background of global accessory and intercostal muscle weakness, or when ventilatory reserve is severely reduced for other reasons, such as asthma or chronic obstructive pulmonary disease (COPD).

Abnormalities in nocturnal gas exchange are harbingers of problems in daytime gas exchange. Hypoventilation during sleep precedes the appearance of daytime hypercapnia, and patients with the most impaired gas exchange during REM sleep have the greatest degree of daytime hypercapnia. Moreover, patients with normal nocturnal gas exchange are unlikely to have abnormal daytime values. Noninvasive (e.g., nasal positive-pressure ventilation, external negative-pressure ventilation) or invasive (e.g., positive-pressure ventilation by tracheostomy) mechanical ventilation improves nocturnal gas exchange and sleep quality, with simultaneous improvement in daytime gas exchange.

Two theories have been proposed to explain the sustained improvements in gas exchange during daytime spontaneous breathing in patients with chronic neuromuscular disease who receive nocturnal ventilatory support. One theory states that nocturnal ventilation rests chronically fatigued respiratory muscles, thereby permitting improved spontaneous ventilation and gas exchange. Although several studies have demonstrated that noninvasive ventilation provides inspiratory muscle fatigue in patients with neuromuscular disease, or that mechanical ventilation consistently increases respiratory muscle strength, evidence that inspiratory muscle fatigue is commonly present in patients with neuromuscular disease or that mechanical ventilation consistently increases respiratory muscle strength is lacking. An alternative hypothesis suggests that nocturnal ventilatory support lowers the central respiratory center CO_2 set point and, thereby, sets the central controller to maintain a lower spontaneous daytime CO_2 level. This hypothesis is supported by studies showing that after several weeks of chronic nocturnal ventilation, hypoventilation was less severe in nocturnal studies without ventilation than it had been on baseline nights before chronic intermittent ventilation. Moreover, interruption of successful nocturnal noninvasive ventilation in patients with neuromuscular disease and chronic respiratory failure results in a return of nocturnal hypoventilation and symptoms of impaired gas exchange without evidence of respiratory muscle dysfunction. To date, neither of the above theories has been established conclusively, and further investigation is warranted, as one or the other, or both, may be valid in different patients.

ASSESSMENT OF RESPIRATORY FUNCTION

Patients with significant respiratory muscle impairment may range from being totally asymptomatic to having moderate dyspnea at rest

TABLE 84-3 Innervation of the Respiratory Muscles

Muscle Group	Innervation	
	Level	Nerve
Upper airway		
Palate, pharynx	IX, X, XI	Glossopharyngeal, vagus, spinal accessory
Genioglossus	XII	Hypoglossal
Inspiratory		
Diaphragm	C3–C5	Phrenic
Scalenes	C4–C8	
Parasternal intercostals	T1–T7	Intercostal
Sternocleidomastoid	X1, C1, C2	Spinal accessory
Lateral external intercostals	T1–T12	Intercostal
Expiratory		
Abdominal	T7–L1	Lumbar
Internal intercostals	T1–T12	Intercostal

or, in some cases, overt respiratory failure. Some patients with neuromuscular disease may have significant weakness of the respiratory muscles and be asymptomatic,[16] whereas others may present with ventilatory failure without an established history of a neuromuscular disease. In the latter patients, the diagnosis of neuromuscular disease may initially be entertained only after difficulty is encountered in weaning the patient from mechanical ventilation. A detailed history and physical examination, coupled with appropriate diagnostic tests, enable the physician to diagnose the presence and type of neuromuscular disease and its effect on the respiratory system. The following section reviews features of the history and physical exam and the diagnostic studies considered useful in the assessment of respiratory function in patients with neuromuscular disease.

In order to provide an organized approach to direct the clinical history-taking and physical examination of patients with neuromuscular disease, Table 84-1 characterizes the types of neuromuscular diseases that present at different levels of the neuromuscular system, and Table 84-3 describes the innervation of the different groups of respiratory muscles.

Clinical History

The signs and symptoms of respiratory muscle weakness due to a neuromuscular disease are usually nonspecific and of limited value. Moreover, the clinical manifestations of respiratory muscle dysfunction depend on the specific muscle or muscles affected and the extent of their impairment. In conditions of mild weakness, or in the early stages of neuromuscular disease, the patient may be totally asymptomatic.[16] As respiratory muscle weakness progresses, however, dyspnea on exertion, followed by dyspnea at rest, occurs. Disturbances in sleep and daytime hypersomnolence resulting from nocturnal hypoventilation may occur, and if the expiratory muscles are affected, patients may have impaired cough and repeated lower respiratory tract infections. As respiratory muscle weakness becomes more severe, hypercapnia or hypoxemia becomes evident and respiratory failure may ensue, requiring ventilatory support.

The clinical history is invaluable in that it may be the first clue that a neuromuscular disease is the cause of the patient's pulmonary dysfunction. A history is also useful in characterizing the type of neuromuscular disease that is present. Dyspnea, and impaired cough with or without recurrent lower respiratory tract infections, may be the first clinical clues that a neuromuscular disease is present. Impaired swallowing due to bulbar symptoms and the presence of peripheral limb muscle weakness are indications that one is dealing with generalized neuromuscular disease.

Physical Examination

Although the physical exam may yield normal results in patients with early or mild impairment of the respiratory system, patients with more established disease often demonstrate tachypnea at rest. Further clinical information on the nature of the underlying disease and the extent of underlying muscle impairment can be gleaned from the pattern of respiratory muscle contraction in both seated and supine positions. Respiratory rate should be recorded along with any evidence of nasal flaring, intercostal muscle retraction, or palpable evidence of contraction of the sternocleidomastoid and scalene muscles. Furthermore, inward paradoxical motion of the rib cage or abdomen should be sought, as its presence may indicate a respiratory workload that is greater than the patient's respiratory muscle strength, or evidence of severe weakness of the diaphragm as a result of the underlying neuromuscular disease. Besides gross paradoxical movement of the rib cage or abdominal compartments, asynchronous compartmental movements (e.g., one compartment moving faster than the other) may be early evidence of impaired respiratory pump performance.

The hallmark finding of severe diaphragm weakness or paralysis is paradoxical inward movement of the abdomen with inspiration. In the presence of severe diaphragm weakness, the upper abdomen moves inward when the upper rib cage moves outward—in stark contrast to the normal pattern of synchronized outward movements of the rib cage and abdominal compartments. Besides paradoxical movement of the upper abdomen, a marked increase in respiratory rate, accompanied by progressive accessory muscle use, and increased dyspnea occur when patients assume the recumbent position due to hypoxemia, hypercapnia, and placing the accessory inspiratory muscles at mechanical disadvantage. Upon reassuming the upright posture, patients may have palpable phasic contractions of the abdominal expiratory muscles. Physiologically, this inward movement of the abdomen on expiration enables passive outward movement of the upper abdomen and diaphragm descent during expiratory muscle relaxation in early inspiration.

Besides a detailed examination of the respiratory musculature and breathing pattern, the physical exam should include a complete neuromuscular examination to exclude systemic involvement. Inspection for atrophy or fasciculations of respiratory and nonrespiratory muscles may point to a lower motor neuron disease. The presence of scoliosis may contribute to the development of restrictive ventilatory pattern.

Radiographic Assessment

In patients with severe inspiratory muscle weakness or bilateral diaphragm paralysis, maximum inspiration is limited, and lung volume appears reduced on chest radiograph. Unilateral hemidiaphragm paralysis produces an elevated hemidiaphragm on the affected side.[17]

Fluoroscopy is often used in the assessment of diaphragm paralysis with the patient making a forceful sniff in the supine position.[17] In unilateral diaphragm paralysis, a positive "sniff" test may demonstrate paradoxical upward movement of the affected hemidiaphragm. However, "sniff" tests have a false-positive rate as high as 6% in normal persons. The use of the "sniff" test to diagnose bilateral diaphragm paralysis is limited by compensatory abdominal muscle contraction. With abrupt cessation of abdominal muscle contraction during early inspiration, the abdominal contents descend caudally. The abdominal wall moves outward, and the diaphragm will then appear to descend caudally, at least radiographically. Besides the fact that passive diaphragm descent due to active abdominal muscle contraction is a limitation during fluoroscopy, the fluoroscopic observational field used to examine the diaphragm is limited because of the small visual band that encompasses only the diaphragmatic dome and adjacent ribs. If rib cage rostral movement exceeds diaphragm ascent, the diaphragm will appear to descend lower than the thorax and may falsely suggest the presence of diaphragm shortening.[18]

Although the diaphragm itself is poorly echogenic, ultrasound can be used to assess its function because the parietal pleura and peritoneal membranes lining the diaphragm are brightly echogenic. The two approaches used are the visualization of the dome or measurement of the muscle thickness at the zone of apposition.[2] Craniocaudal movement of the dome of the diaphragm can be measured by placing an ultrasound probe on the upper abdomen or on the lateral chest. This technique has compared favorably with the traditional fluoroscopic procedures used to assess diaphragm movement. Because the costal portion of the diaphragm is close to the skin, the zone of apposition is an ideal area to use ultrasound for assessment of the diaphragm thickness and estimation of length. The thickness of the diaphragm increases with increasing lung volumes and is inversely proportional to its length. Measurement of the zone of apposition will permit the detection of diaphragm contraction during inspiratory efforts when trying to diagnose diaphragm paralysis. As the subject with diaphragm paralysis makes an inspiratory effort there will not be thickening of the diaphragm at the zone of apposition. Measurement of the thickness also allows for the assessment of atrophy or the effect of neuromuscular diseases.

■ Arterial Blood Gas Analysis

Arterial blood gas abnormalities usually occur only in patients with severe respiratory muscle weakness. Hypoxemia is usually mild and may occur as a result of macroatelectasis and subsequent intrapulmonary shunting or ventilation–perfusion mismatch. In addition, patients with impaired muscle strength have impaired cough and may retain secretions that further contribute to the development of hypoxemia. Measurement of arterial oxyhemoglobin saturation by pulse oximetry, which has become an extremely common laboratory test for oxygenation, is an insensitive indicator of hypoventilation. In patients with mild to moderate respiratory muscle weakness, the value of solely measuring the level of oxygenation is limited and may be misleading.

Hypercarbia is an insensitive measure of respiratory muscle strength. The Pa_{CO_2} does not increase until respiratory muscle strength (measured by maximum inspiratory and expiratory mouth pressures) is less than 50% of predicted. In patients with severe respiratory muscle weakness, however, an elevation in Pa_{CO_2} may be evident. Serum bicarbonate and arterial pH values may help determine whether an acute or chronic respiratory acidosis is present. Because daytime hypercapnia is usually followed by nocturnal hypoventilation, the presence of daytime hypercapnia should prompt investigation of the breathing pattern and gas exchange during sleep, so that appropriate therapy (e.g., nocturnal supplemental oxygen or noninvasive ventilation) can be implemented.

■ Respiratory Muscle Strength

A variety of tests can be used to assess respiratory muscle strength. Each is discussed below.

Maximum Mouth Pressures

Maximum static inspiratory and expiratory mouth pressures, measured at the airway opening during a voluntary contraction against an occluded airway, are the simplest and most commonly performed tests of respiratory muscle strength. Although several methods exist, the technique of Black and Hyatt is still the most widely used.[19] In this technique, mouth pressures are measured using a handheld manometer with the patient seated upright with a nose clip on. During these maneuvers, the patient purses the lips inside a circular wide-bore rubber mouthpiece, which prevents perioral air leakage. This small orifice (2 mm in diameter, 15 mm in length) is placed in the circuit to minimize the contribution of the facial muscles to airway pressure and to keep the glottis open. Maximum inspiratory pressures (PI_{max}) are measured near residual volume after maximal expiration, while maximal expiratory pressures (PE_{max}) are measured at or near total lung capacity. In each case, efforts are maintained for at least 1 s. Maximum inspiratory and expiratory mouth pressures in normal males and females are listed in Table 84-4. Reported values in normal subjects vary widely and may be due to differences in techniques between different studies or a learning effect in subjects who perform these maneuvers.[20–25]

TABLE 84-4 Reported Values for Maximum Static Airway Pressures in Normal Adults

Study	Sex	No. of Subjects	Age Range (Years)	PI_{max} (cm H_2O)	PE_{max} (cm H_2O)
Black and Hyatt[20]	Males	60	20–54	124 ± 22	233 ± 42
	Females	60	20–54	87 ± 16	152 ± 27
Ringqvist[25]	Males	100	18–83	130 ± 32	237 ± 46
	Females	100	18–83	98 ± 25	165 ± 30
Leech et al.[22]	Males	325	17–35	114 ± 36	154 ± 82
	Females	480	15–35	71 ± 27	94 ± 33
Rochester Arora[21]	Males	80	19–49	127 ± 28	216 ± 41
	Females	121	19–49	91 ± 25	138 ± 39
Vincken et al.[24]	Males	46	16–79	105 ± 25	140 ± 38
	Females	60	16–79	71 ± 23	89 ± 24
Wilson et al.[23]	Males	48	19–65	106 ± 31	148 ± 34
	Females	87	18–65	73 ± 22	93 ± 17

Values are mean ± standard deviation.

A major factor affecting PI_{max} is lung volume. PI_{max} is greatest at residual volume, whereby the inspiratory muscles are at greatest mechanical advantage and the outward elastic recoil of the respiratory system is maximum. On the other hand, measurement of PE_{max} is greatest at total lung capacity because expiratory muscles are at greatest mechanical advantage and inward elastic recoil of the respiratory system is greatest (Fig. 84-5). Only at functional residual capacity, where the respiratory system recoil pressures measured at the airway opening are zero, are maximum inspiratory and expiratory mouth pressures solely a function of the pressure generated by actively contracting respiratory muscles (P_{mus}).

Changes in lung volume due to chest wall or lung pathology may have important effects on the generation of maximum respiratory pressures in patients. For example, patients with COPD and significant hyperinflation have a larger FRC and residual volume than normal subjects; therefore, PI_{max} performed at FRC or RV usually results in lower values than in age- and sex-matched normal subjects. Likewise, a reduction in total lung capacity due to restrictive ventilatory diseases may result in a reduction in measured values for PE_{max}. Therefore, it is important to realize that in patients with pathologically altered lung volumes, all or part of the reduction in mouth pressures may be due to inspiratory muscle mechanical disadvantage.

Maximum inspiratory and expiratory mouth pressures in patients with neuromuscular diseases range from normal to severely reduced. Patients may have significant respiratory muscle weakness without

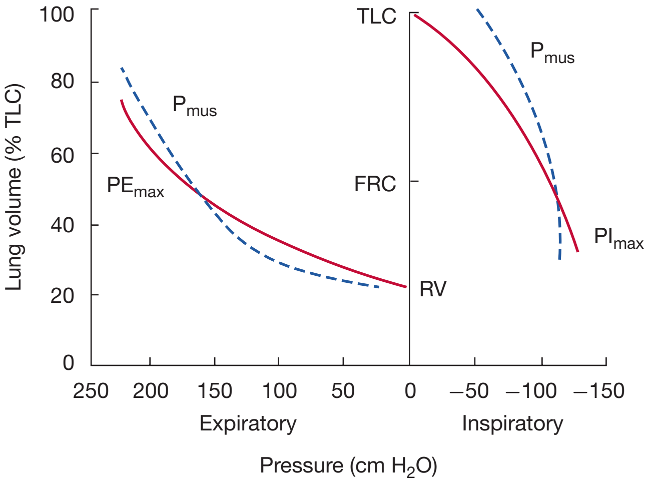

Figure 84-5 The effect of lung volume on maximum respiratory pressures (PI_{max} and PE_{max}) measured at the airway opening displayed by *solid lines*. Both PI_{max} and PE_{max} are made up of two components: the pressure generated by the respiratory muscles (P_{mus}, *dashed lines*) and the recoil pressure of the respiratory system. Only at FRC when recoil pressures are zero are PE_{max} and PI_{max} solely due to P_{mus}.

any pulmonary complaints, and no correlation exists between respiratory muscle strength and the presence of generalized nonrespiratory muscle weakness.[16] When PI_{max} falls below 30 cm H_2O, ventilatory failure commonly ensues.

The assessment of a patient's ability to generate an effective cough is extremely important when managing the pulmonary effects of neuromuscular diseases. Nearly all these disorders result in weak cough, which puts the individual at risk for aspiration and pneumonia. While a normal PE_{max} ensures that the patient has adequate cough, a low PE_{max} could result from poor effort, bulbar weakness not allowing a tight seal around the mouthpiece, or true expiratory muscle weakness. Therefore, there is interest in developing a test that will allow the assessment of cough strength in a nonvolitional manner. Measurement of positive pleural pressures with an esophageal balloon during a forceful cough ($P_{es\ cough}$) has also been proposed as a measure of expiratory muscle strength. $P_{es\ cough}$ has been shown to decrease in parallel with PE_{max} when expiratory muscle weakness is induced by progressive curarization. A study examined the use of measurement of gastric pressures during cough ($P_{ga\ cough}$) in a group of normal subjects and in those with suspected respiratory muscle weakness from pulmonary and neuromuscular disease. The measurement of $P_{ga\ cough}$ is theoretically better because it takes into account the abdominal musculature, it eliminates the problem of leak around the mouthpiece, and a cough maneuver is easier to perform than the PE_{max} maneuver. In 122 patients with a normal PE_{max}, more than 95% also had a normal $P_{ga\ cough}$, but in 171 patients with a low PE_{max} 72 had a normal $P_{ga\ cough}$ suggesting a high false positive rate of a low PE_{max}. Conversely, in 105 patients with a low $P_{ga\ cough}$ only 6 had a normal PE_{max} suggesting a low false-positive rate for a low $P_{ga\ cough}$.[26]

Transdiaphragmatic Pressure Measurement

While maximum static airway pressures are useful measures of global respiratory muscle strength, they fail to assess individual respiratory muscle function. Since the diaphragm is the primary muscle of inspiration, and may be susceptible to isolated disease (e.g., phrenic nerve paralysis after open-heart surgery or idiopathic diaphragm paralysis), specific testing of diaphragm strength is desirable in some patients. Assessment of diaphragm strength is made by measuring gastric (P_{ga}) and endoesophageal (P_{es}) pressures with balloon-tipped catheters placed in the stomach and midesophagus, respectively. Transdiaphragmatic pressure (P_{di}) is then calculated as the algebraic subtraction of P_{es} from P_{ga} ($P_{di} = P_{ga} - P_{es}$).[2]

Maneuvers to elicit maximum transdiaphragmatic pressures (Pdi_{max}) have been the subject of intensive study. Earlier studies measured Pdi during maximum static inspiratory efforts against a closed airway (e.g., the Mueller maneuver) at FRC or RV. However, this maneuver results in submaximal diaphragm activation, with the degree of activation varying widely from subject to subject. Several studies have demonstrated significant intraindividual variability, with a coefficient of variation as high as 40% in measurement of Pdi_{max} during the Mueller maneuver. When five maneuvers to measure Pdi_{max} in 35 subjects (10 normal, 13 with restrictive lung disease, and 12 with COPD) were compared, a combined maneuver of active expulsion with superimposed Mueller maneuver yielded the most reproducible and maximal transdiaphragmatic pressure.[27]

Phrenic Nerve Stimulation

A crucial factor in the measurement of diaphragm strength is the ability to consistently obtain maximal activation of the diaphragm during volitional efforts. Electrophrenic stimulation is a method that has been utilized to consistently activate the diaphragm. Besides assessing diaphragm strength, this technique has the added advantage of assessing phrenic nerve conduction and excluding the possibility of phrenic nerve injury in patients with diaphragm weakness of unknown origin.[2]

The phrenic nerve is stimulated in the neck near the posterior border of the sternocleidomastoid muscle, at the level of the cricoid cartilage, where the phrenic nerves are most superficial. Stimulation may be performed either transcutaneously with surface electrodes (electrical stimulation electrodes) or magnetic coil, or percutaneously with needle or wire electrodes. The percutaneous method is rarely used now. Stimulation of the phrenic nerves must be supramaximal with regard to voltage and current. Supramaximal conditions are ensured by increasing the stimulus intensity until maximum diaphragm muscle action potential (DMAP) or P_{di} is achieved. The DMAP is measured by surface EMG electrodes, and the P_{di} is measured by measuring the esophageal and gastric pressures via two pressure transducers as described above. The DMAP is then checked periodically throughout the study to ensure that consistent stimulation is maintained.[2,28]

The most commonly used technique of electrophrenic stimulation now employs a frequency of one pulse per second to measure P_{di} during a single unfused twitch contraction (i.e., $P_{di,tw}$). $P_{di,tw}$ has also been used to assess maximal static P_{di} indirectly by the twitch occlusion technique.[2,29] In this method, single twitches are superimposed on progressively stronger voluntary P_{di} contractions. As voluntary effort and P_{di} increase, the increment in P_{di} produced during the twitch (the twitch deflection superimposed on the P_{di}) decreases (Fig. 84-6A). When there is no discernible $P_{di,tw}$ deflection, it is assumed that the diaphragm is maximally activated. If the $P_{di,tw}$ does not go to zero then the extrapolation of the line of this relationship to the X-axis has been interpreted as representing maximum static P_{di} (Fig. 84-6B).

An alternate way to perform phrenic nerve stimulation is via magnetic stimulation.[2,30] In this technique, an electric current is run through a coil thereby producing a magnetic field. The coil is placed over the spinous process of the seventh cervical vertebral body (cervical magnetic stimulation) stimulating the C3–C5 cervical roots of the phrenic nerve and causing the diaphragm to contract. Magnetic stimulation of this area will also stimulate contraction of neck and upper rib cage muscles as well. The advantages of this technique are that it is less painful than the electrical stimulation method, and it is easier to evoke diaphragm contractions. Also, it is possible to perform magnetic stimulation of the phrenic nerve while the patient is

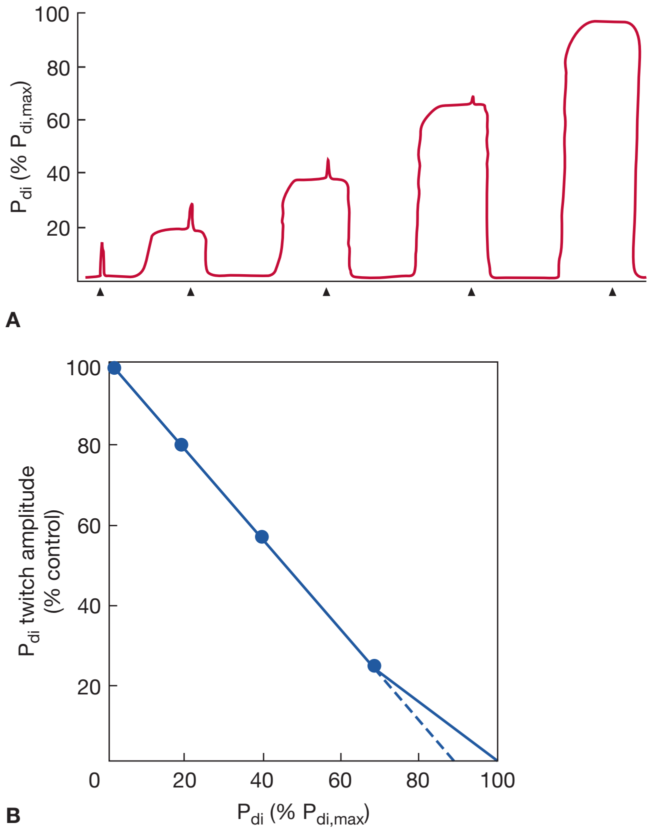

Figure 84-6 **A.** Illustration of a typical P_{di} tracing during twitch occlusion study. As the P_{di} increases during volitional efforts, the superimposed P_{di} deflection during phrenic nerve 1-Hz stimulation (twitch) decreases. At 100% of $P_{di,max}$, the diaphragm is maximally activated and no superimposed twitch is seen. *Arrows* on the horizontal axis mark indicate the phrenic nerve twitches. **B.** Data from A plotted as $P_{di,tw}$ amplitude versus voluntary P_{di}. Using linear regression, $P_{di,max}$ can be extrapolated from results obtained during submaximal efforts. It has been suggested that extrapolation performed from P_{di} values below 70% of maximum may underestimate $P_{di,max}$ by approximately 10% *(dashed line)*.

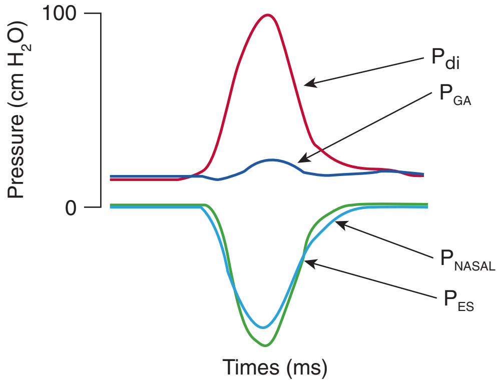

Figure 84-7 Pressure tracing produced utilizing sniff maneuver in a normal individual with gastric and esophageal balloon manometry in place. The noninvasive P_{NASAL} pressure closely mirrors that of the invasive P_{ES}. P_{GA}, gastric pressure; P_{di}, transdiaphragmatic pressure; P_{ES}, esophageal pressure; P_{NASAL}, nasal pressure during sniff maneuver.

in the supine position by placing the magnetic coil anterior to the sternum. This would allow for hospitalized bedbound patients to be evaluated for diaphragm weakness via phrenic nerve stimulation. One of the disadvantages of magnetic stimulation is that it lacks the specificity that electrophrenic stimulation has for the diaphragm, and obtaining an EMG_{di} signal can be more difficult with magnetic stimulation. When comparing magnetic stimulation $P_{di,tw}$ to electrophrenic $P_{di,tw}$, the $P_{di,tw}$ tends to be 20% to 25% higher with magnetic stimulation.

In addition to assessing diaphragm strength, phrenic nerve stimulation can be used to assess phrenic nerve function. The EMG_{di} is measured via surface or esophageal electrodes during electric or magnetic phrenic nerve stimulation, and the phrenic nerve conduction time can be measured.[2] This measurement is useful when assessing possible injury to the phrenic nerve from thoracic surgery, trauma, or neuropathies (e.g., critical illness polyneuropathy or Guillain-Barré syndrome). The normal conduction time via electrical stimulation is 7.5 to 9 ms, but the normal conduction time via magnetic stimulation has not been well defined because activation of the brachial plexus affects the phrenic nerve conduction time. However, Luo et al. demonstrated that if the magnetic coil is placed anteriorly to the cricoid cartilage, then the phrenic nerve conduction time was very similar to that obtained by electric stimulation. The authors believe that this occurred because there was more brachial plexus activation in the lower position compared with the higher position.[31]

Because of the relative invasiveness of electrophrenic stimulation of the diaphragm, and the large coefficient of variation in some studies when P_{di} was measured during maximal volitional efforts, some investigators prefer measuring maximum inspiratory pressures during a sniff maneuver (Fig. 84-7). In this technique, the subject performs a vigorous sniff against an unoccluded airway. During such an effort, the nose acts as a Starling resistor, thereby generating intrathoracic pressures against an occluded airway. Some investigators argue that this maneuver approaches a more natural respiratory effort than other types of maneuvers used to measure maximum inspiratory pressures and thus should be easily mastered by patients and more reproducibly performed by technicians.[32]

Analysis of Rib Cage and Abdominal Motion

During normal tidal breathing, the chest and abdominal compartments move synchronously in an outward direction, owing to diaphragm contraction decreasing pleural pressure and increasing abdominal pressure. In situations where the diaphragm is severely paretic or paralyzed, however, the flaccid diaphragm cannot counterbalance the negative changes in pleural pressure generated by contraction of the inspiratory muscles of the neck and rib cage. Instead of moving normally in a caudal direction the flaccid diaphragm moves paradoxically cephalad into the thorax. This change in diaphragm motion gives rise to a paradoxical inward motion of the upper abdomen indicative of severe diaphragm weakness or paralysis.

Changes in rib cage and abdominal pressure, or volume displacement during respiration, can provide important information about diaphragm strength. Partitioning of respiration can be examined from changes in abdominal and pleural pressures, as proposed by Macklem et al.[33] Changes in abdominal and pleural pressures during inspiration, expressed as the ratio of delta P_{ab}:delta P_{PL} are normally negative as pleural pressure becomes more negative and abdominal pressure becomes more positive. This ratio has a maximum value of +1 when the diaphragm does not contribute to inspiration and is valid only if the expiratory muscles do not contribute significantly to the pressures being generated. Alternatively, the partitioning of ventilation can be noninvasively measured by compartmental changes in rib cage and abdominal volume by respiratory inductance plethysmography or magnetometry. Optoelectronic plethysmography (OEP) is a technique that allows for measurement of chest wall and abdominal motion as well as lung volumes. A series of 89 retroreflective markers are placed on the thorax and abdomen that are monitored by a series of 6 to 8 cameras (Fig. 84-8). The cameras record

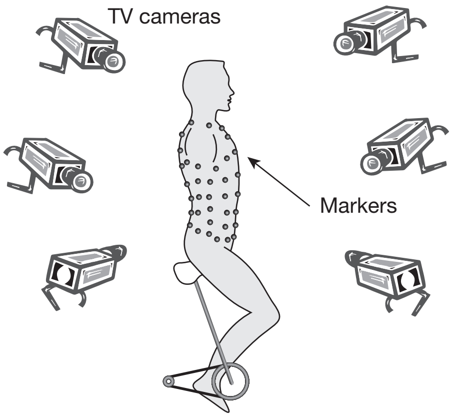

Figure 84-8 An example of optoelectronic plethysmography. A series of markers are placed on the subject's thorax and abdomen. A group of cameras record the distance the markers move in all planes thus permitting calculation of lung volumes during the breathing cycle. *(Reproduced with permission from Vogiatzis I, Aliverti A, Golemati S, et al. Respiratory kinematics by optoelectronic plethysmography during exercise in men and women. Eur J Appl Physiol. 2005;93(5-6):581–587.)*

the distance the markers move in space, and using Gauss' theorem the total thoracoabdominal lung volume can be calculated. OEP can differentiate between volume generated by the rib cage (rib cage musculature) and volume generated by the abdomen (diaphragm).[34] OEP can also be used to measure flow and is a nonvolitional test that can be done in any spontaneously breathing individual without regard to the degree of muscle weakness.[34] This technique has been used in patients with Duchenne muscular dystrophy to show that with disease progression the proportion of the tidal volume attributable to the abdomen decreases while the tidal volume attributable to the rib cage increases. Furthermore, those that had this change in breathing pattern were more likely to have nocturnal desaturation.[35]

Spirometry

Respiratory muscle weakness induced by neuromuscular disease produces a restrictive pattern on spirometric testing with a reduction in VC.[6] As previously mentioned, the reduced VC is commonly out of proportion to the reduction in maximal respiratory muscle force. Reductions in lung and chest wall compliance also probably contribute. Moreover, because of the contour of the pressure–volume curve, large reductions in the respiratory muscle forces have to occur before VC is significantly reduced. A decrease in VC greater than 25% on moving from the upright to supine postures has been used as a sign of diaphragmatic weakness and a greater likelihood of sleep-related hypoventilation.[14,36]

Forced expiratory volume in 1 s (FEV_1) and measurements of midexpiratory flow rates (FEF_{25-75} or FEF_{50}) are often greater than normal predicted values in patients with neuromuscular disease. Further increases in expiratory flow may occur in patients with neuromuscular disease due to increased lung recoil. Two independent studies have shown that partial curarization in normal subjects produces a decrease in peak expiratory flow with an increase in midexpiratory flow rates compared with baseline.[3,37] Moreover, in patients with myasthenia gravis in their baseline state of weakness before the administration of pyridostigmine, midexpiratory flow rates are increased over the range of vital capacity when referenced to absolute lung volume[6] (Fig. 84-9).

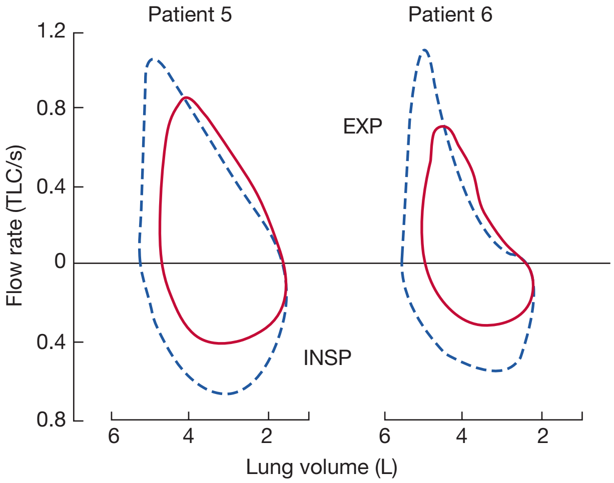

Figure 84-9 Two representative patients with myasthenia gravis and respiratory muscle weakness illustrating the effect of anticholinesterase therapy on maximum flow–volume curves. *Solid curves* represent pretreatment data; *dashed curves* were obtained following the injection of pyridostigmine. Prior to administration of pyridostigmine the midexpiratory flow rates were greater even though respiratory muscles were weaker and lung volumes were lower. *(Reproduced with permission from DeTroyer A, Borenstien S. Acute changes in respiratory mechanics after pyridostigmine injection in patients with myasthenia gravis. Am Rev Respir Dis. 1980;121(4):629–638.)*

Flow–Volume loops

Changes in the configuration of the flow–volume loop occur in various neuromuscular diseases.[2,38,39] These changes reflect respiratory muscle weakness or malfunction of upper-airway muscles. "Sawtoothing" of the flow contour is seen in extrapyramidal disorders affecting upper-airway muscles.[40] Similarly, plateauing of the inspiratory flow wave form indicative of extrathoracic airway obstruction has been described in vocal cord paralysis caused by extrapyramidal neuromuscular disorders. An abnormal flow–volume curve is significantly more common in patients with clinically apparent bulbar muscle involvement (90% vs. 15%, respectively), and the presence of an abnormal flow–volume loop predicted bulbar and upper muscle involvement by a neuromuscular disease with a high sensitivity and specificity.[41] A characteristic flow–volume contour showing involvement of the upper-airway muscles by motor neuron disease is shown in Fig. 84-10.

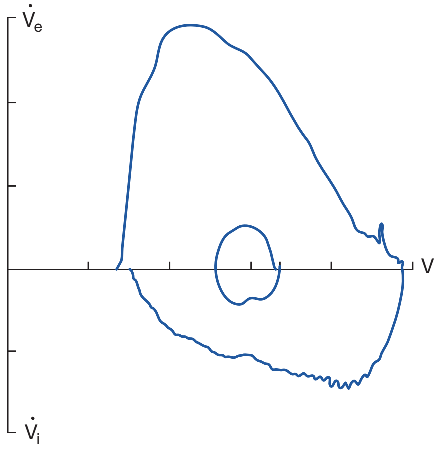

Figure 84-10 Flow–volume loop in a patient with motor neuron disease, showing inspiratory flow oscillation and inspiratory flow limitation. Subdivisions on volume and flow axis represents 1 L, flow axis 1 L/s. *(Data from Vincken W, Elleker MG, Cosio MG. Determinants of respiratory muscle weakness in stable chronic neuromuscular disorders. Am J Med. 1987;82(1):53–58.)*

Among patients with stable, chronic neuromuscular disease, the flow–volume loop is significantly more disturbed in those with respiratory muscle weakness, and these abnormalities correlate with reduced mouth pressures. Several features of flow–volume loop configuration correlate with reduced maximum static inspiratory and expiratory mouth pressures: a reduced peak expiratory flow, a decreased slope of the ascending limb of the maximum expiratory curve, a drop-off of forced expiratory flow near residual volume, and a reduction in forced inspiratory flow at 50% of vital capacity (Fig. 84-11). A flow-volume loop score composed of the above parameters has a high degree of specificity and 90% sensitivity in predicting respiratory muscle weakness.[41]

Lung Volumes

A restrictive ventilatory pattern is demonstrated in patients with neuromuscular disease. A reduced TLC and a normal or reduced FRC are common. The RV is usually elevated and is a sign of expiratory muscle weakness.

Maximum Voluntary Ventilation

Maximum voluntary ventilation (MVV) is an index of respiratory muscle endurance in the presence of normal expiratory flow rates. This appears to be appropriate in patients with neuromuscular disease, since airway resistance and FRC are usually within the normal range. Values for MVV correlate with respiratory muscle strength and may be even more sensitive than VC in detecting respiratory muscle weakness.[2]

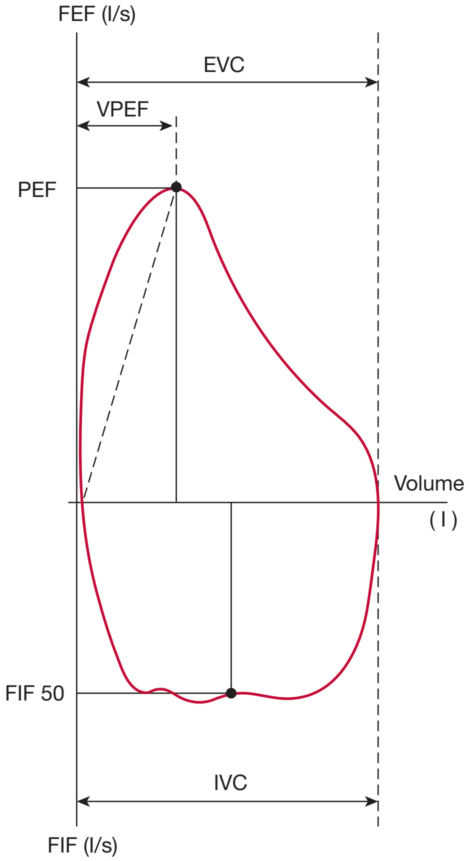

Figure 84-11 Representative flow–volume loop of a patient with chronic neuromuscular disease, showing different volume loop parameters indicative of respiratory muscle weakness. These parameters quantify the effects of respiratory muscle strength on the effort-dependent portions of the flow–volume loop. These four parameters are peak expiratory flow (PEF); ratio of PEF to the exhaled volume at which PEF was achieved, rapid vertical drop of forced expiratory flow at residual volume, and forced midinspiratory flow. *(Data from Vincken W, Elleker MG, Cosio MG. Determinants of respiratory muscle weakness in stable chronic neuromuscular disorders. Am J Med. 1987;82(1):53–58.)*

SELECTED NEUROMUSCULAR DISEASES

A helpful approach toward understanding how specific neuromuscular diseases affect the respiratory system is to localize the anatomic involvement of the respiratory system. A detailed description of the neuroanatomy of respiration is outside the scope of this chapter and is covered elsewhere in this text. In general, however, neuromuscular disorders can be broken down into disorders that involve the upper motor neuron, the lower motor neuron, or the muscle itself.

Lesions that arise in the cerebral cortex, brain stem, or spinal cord are classified as upper motor neuron lesions and are characterized by an increase in muscle tone or spasticity, the presence of an extensor plantar response, and increased reflex activity. Lesions in the lower motor neuron system demonstrate flaccidity, depressed reflexes, muscular fasciculations, and atrophy. The location and character of the patient's weakness may enable one to identify the exact site of the lesion in the lower motor neuron system (i.e., the anterior horn cell, the peripheral nerve, the neuromuscular junction, or the muscle itself).

The following describes the effect of specific neuromuscular disease on the respiratory system and makes recommendations for treatment.

■ Upper Motor Neuron Lesions

Below we consider the respiratory effects of stroke, spinal cord injury, Parkinson disease, and multiple sclerosis.

Stroke

Hemispheric ischemic strokes reduce chest wall and diaphragm movement on the side contralateral to the cerebral insult. Decreased diaphragm excursion with stroke correlates with diaphragmatic cortical representation identified by transcranial magnetic stimulation. Bilateral hemispheric strokes are also associated with Cheyne-Stokes respiration, which is progressive hyperventilation alternating with hypoventilation and ending in apnea. This breathing pattern may result from increased responsiveness to carbon dioxide as result of interruption of normal cortical inhibition. The significance of Cheyne-Stokes respiration to stroke remains unclear but it appears to be more common with bilateral than unilateral insults. Besides its effects on an alteration of breathing pattern, up to 50% of patients with strokes may have signs of pulmonary aspiration due to dysfunction of upper-airway muscles that protect the airway.

Spinal Cord Injury

The degree of respiratory impairment depends on the level and extent of the spinal cord injury. High cervical cord lesions (C1 to C3) cause paralysis of the diaphragmatic, intercostal, scalene, and abdominal muscles. Because all respiratory muscle activity is lost except for accessory and bulbar muscle function, high cervical cord injuries almost always require ventilatory assistance. In some patients, spontaneous breathing can be accomplished by glossopharyngeal breathing or diaphragmatic pacing because the phrenic nerve motor neurons (C3–C5) remain intact.

Middle cervical cord (C3–C5) lesions destroy the phrenic motor neurons and prohibit the use of phrenic nerve pacing. Patients with more caudal lesions (i.e., C4–C5 level) have an improved chance to wean from ventilator support compared to those with more cranial lesions. (Forty percent of patients with C3 lesions remain ventilator dependent.) Patients with lower cervical (C6–C8) and upper thoracic (T1–T6) cord lesions have intact diaphragm and neck accessory muscle action but have denervated intercostal and abdominal muscles. These patients usually require ventilatory support only during the period immediately after the injury and rarely require long-term ventilation. Despite this these patients still have increased mortality. In a group of spinal cord injury patients not requiring mechanical ventilation or tracheostomy followed prospectively for a median of 4.5 years, predictors of death included age, cardiac disease, diabetes, smoking history, and lower FEV_1.[42] The decline in FEV_1 and FVC in these patients is related to aging, increasing BMI, smoking, persistent wheeze, and lower MIP.[43] These data suggest that there are modifiable risk factors that can be altered to improve outcomes in those with spinal cord injuries that do not require mechanical ventilation.

In a study of C5 or lower spinal cord injured patients, inspiratory muscle strength was reduced to approximately 60% of predicted but was dependent on the level of cord injury. In this study, PI_{max} values in low cervical, midthoracic, and lower thoracic–upper lumbar lesions were 61%, 69%, and 75% of predicted, respectively, whereas PE_{max} values were 30%, 32%, and 54% of predicted, respectively. The lower PE_{max} values were explained by a paralysis of abdominal and intercostal muscles resulting in reduced cough and decreased clearance of bronchial secretions. Abdominal muscle paralysis probably accounts for an abnormally compliant abdomen in patients with lower spinal cord injury, which is in stark contrast to the 30% reduction in chest wall compliance believed due to abnormal rib cage stiffness.[8]

Patients with spinal cord injuries also have alterations in thoracoabdominal motion during tidal breathing that is further accentuated by changing from the erect to supine position. In quadriplegic patients with relatively intact diaphragm function, the distribution of respiratory muscle weakness results in paradoxical inward motion of the upper rib cage during inspiration owing to weakness of the parasternal and scalene muscles. This pattern of abnormal thoracoabdominal movement is more marked in the supine than in the upright position. Patients with high quadriplegia (above C3–C5) may be able to sustain short periods of spontaneous respiration because of inspiratory activity of the sternocleidomastoid and trapezius muscles. Phasic inspiratory electromyography (EMG) activity has been observed in the platysma, mylohyoid, and sternohyoid muscles. Analysis of ribcage motion in these patients shows increased upper rib cage diameter due to the inspiratory action of the neck accessory muscles pulling the sternum cranially and expanding the upper rib cage.

The distribution of muscle paralysis in low cervical cord spinal patients also has a profound effect on the performance of forced expiratory maneuvers. In contrast to healthy normal subjects, in whom VC is moderately decreased on assuming the supine position, in quadriplegic patients there is a paradoxical increase in VC in the supine compared to seated position without a significant increase in TLC. In 14 quadriplegic patients (C4–C7), there was a 16% increase in VC on changing from the upright to supine position and a reduction in RV (29%) and TLC (on average, 6%).[44] The mechanism believed to be responsible for the increase in VC in supine quadriplegic patients is the hydrostatic effect of abdominal contents, causing cephalad displacement and diaphragm lengthening and thereby placing the diaphragm on a more favorable portion of its length tension curve. The use of elastic binders when quadriplegics assume upright posture has been advocated to prevent the increase in abdominal compliance. Abdominal binding may have physiologic benefit by maintaining diaphragm precontraction length in a more optimum position on its length-tension curve.[45]

It was previously believed that all expiratory muscles were paralyzed in lower cervical cord injuries. However, studies of C5 to C8 quadriplegics indicate that phasic EMG activity of the clavicular portion of the pectoralis major is associated with a marked decrease in the anteroposterior diameter of the upper rib cage.[46] This portion of the pectoralis muscle receives innervation from the C5 to C6 cord level. With the arms placed at the subject's side, contraction of the caudate head of the pectoralis major causes caudal displacement of the manubrium sterni and upper rib cage. This expiratory action has been shown to decrease expiratory reserve volume (ERV) by 60% when the shoulders are held in abduction. After 6 weeks of pectoralis muscle isometric training, patients with low quadriplegia can have a marked increase in maximum pectoralis muscle isometric strength and a significant reduction in ERV.[47] Conceivably, therefore, training of this muscle could improve the effectiveness of cough in patients with low spinal cord injury.

In the months following spinal cord injury, pulmonary function typically improves. In patients with spinal injuries below the C5 level, VC is approximately 30% of predicted in the first week after injury but increases to 45% of predicted by the fifth week—and by the fifth month to approximately 60% of predicted.[48] Improvements in VC have been attributed to spasticity developing in previously flaccid intercostal and abdominal muscles thereby increasing the rigidity of the thorax and abdomen and improving diaphragm force generation.

There is a role for corticosteroid use in the acute management of spinal cord injury. Methylprednisolone given as a 30-mg/kg bolus followed by a 24-h infusion at 5.4 mg/kg/h has been shown to improve motor function at 6 weeks, 6 months, and 1 year, but only in those who received the drug within 8 h of injury.[49] A subsequent study compared methylprednisolone infusion (5.4 mg/kg/h) for 48 h to 24 h after the administration of a bolus (30 mg/kg).[50] There was no difference in functional outcome between the two infusion periods except in those where the bolus dose was given between 3 and 8 h after the injury. If the methylprednisolone was started between 3 to 8 h after the injury, then those that received the infusion for 48 h did have improved motor function at 6 weeks and 6 months. There were higher rates of pneumonia and sepsis in the 48-h infusion group, but mortality was not different.[50] No trial has shown a mortality benefit, and it should be recognized that the outcome measured was an improvement in the functional independence measure (FIM) score and not a return to normal motor function.

Parkinson Disease

Parkinson disease is due to degeneration of neurons in the substantia nigra and has a prevalence in the United States of approximately 200 cases per 100,000 people. Parkinson disease can be either primary (e.g., idiopathic) or secondary, as in postencephalitic parkinsonism associated with the influenza pandemic, or part of a more generalized disorder, such as multiple system atrophy or drug abuse with MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine).

Parkinson disease has been thought to be a purely motor disorder, but recently nonmotor findings are being associated with Parkinson disease and can predate motor symptoms.[51] These findings have led to speculation that Parkinson disease could alter respiratory control at the level of the brainstem. A study in 15 subjects with early Parkinson disease and normal respiratory flow and volumes found that 7 of 15 had an abnormal ventilatory response while 11 of 15 had an abnormal occlusion pressure response ($P_{0.1}$) to hypercapnic challenge testing, suggesting abnormal respiratory control.[52]

Respiratory abnormalities are common in Parkinson disease, with pneumonia being the most common cause of death. A substantial problem with Parkinson disease is glottic muscle dysfunction.[53] An abnormal flow–volume loop contour showing flow oscillations commonly occurs. On direct fiberoptic visualization of the upper airway, these oscillations correspond to rhythmic involuntary movements of glottic and subglottic structures. Physiologic evidence of upper-airway obstruction may be present. In addition to the presence of oscillations in flow, a rounding off of the peak of the midexpiratory flow–volume curve, a lowered peak expiratory flow rate, and a delayed appearance of peak expiratory flow have been observed in Parkinson patients. These results have been interpreted as evidence for less coordinated or less "explosive" respiratory muscle contractions.[38,40]

Patients with mild to moderate Parkinson disease are able to perform simple single respiratory efforts (e.g., measurements of lung volume and maximum static inspiratory pressures) but have difficulty performing more complex, repetitive ventilatory efforts (i.e., sustaining inspiratory resistive loads to exhaustion and performing maximum unloaded breathing efforts). Performance of repetitive respiratory tasks is associated with an increased work of breathing when compared with that of an age-matched control group. These findings are similar to derangements in task performance exhibited by peripheral skeletal muscle groups in Parkinson patients.[54]

Treatment significantly improves neurologic scores, maximum expiratory pressures, and peak inspiratory flow. A recent meta-analysis has demonstrated that levodopa improves peak expiratory flow and FVC in Parkinson disease.[55] Deep brain stimulation by stereotactically placing electrodes into the suprathalamic nucleus or the globus pallidus nucleus has been shown to be equally effective when treating medically resistant patients.[56] The electrodes produce a low-voltage high-frequency stimulation that results in inhibition of the neurons in the nucleus. Although the effect on respiratory function has not been directly studied, this procedure has been shown to improve motor function and quality of life.[57]

Multiple Sclerosis

Multiple sclerosis (MS) is a demyelinating disorder of the central nervous system, characterized clinically by remissions and relapses of clinical symptoms due to disseminating CNS lesions. MS is the most common neurologic disease afflicting young adults, with an estimated prevalence of more than 2 million affected individuals worldwide and 400,000 cases in the United States.[58] The disease is associated with fully or partially reversible episodes of neurologic disability typically lasting days to weeks (relapsing-remitting course). While 15% of patients will have a progressive course from symptom onset (primary progressive MS), most will not develop progressive symptoms for 10 to 20 years.[58] The progressive deterioration is characterized most commonly by impaired ambulation, bladder incontinence and impaired cognition. The cause of MS is unknown, although epidemiologic evidence points to genetic and environmental factors. Classic clinical symptoms include paresthesia, motor weakness, diplopia, blurred vision, dysarthria, bladder incontinence, and ataxia.

Because MS can cause focal lesions anywhere in the central nervous system, different patterns of respiratory impairment can occur. Impairment of the respiratory centers and the medulla can cause failure of automatic breathing (Ondine's curse) and apneustic or neurogenic pulmonary edema. The three most common respiratory manifestations of MS are respiratory muscle weakness, bulbar dysfunction, and abnormalities in respiratory control. Despite advances in treatment MS is associated with a decreased life expectancy. MS rarely is the sole cause of death but rather death results from complications of the disease. A recent population-based study of death certificate data on adults from British Columbia, Canada demonstrated that aspiration pneumonia (OR, 7.15; CI, 6.23–8.22) and respiratory infection (OR, 3.03; CI, 2.73–3.36) were among the most common contributors to death in patients who had MS listed on their death certificate.[59]

Acute respiratory failure rarely occurs in this disease, but it can occur because of severe demyelination of the cervical cord. Diaphragmatic paralysis resulting in respiratory insufficiency also has been reported. Even with severe disability and impaired respiratory muscle strength, patients with MS seldom complain of dyspnea. This paucity of respiratory complaints may be due to restricted motor activities and greater expiratory than inspiratory muscle dysfunction. Clinical signs that may be helpful in predicting respiratory muscle impairment are weak cough and inability to clear secretions, limited ability to count on a single exhalation, and upper extremity involvement. Advanced MS is frequently complicated by aspiration, atelectasis, and pneumonia.

In a group of 38 patients who were not bedridden or wheelchair-bound without bulbar involvement and a diagnosis of MS for 9.2 years, there was a significant decrease in the maximal inspiratory pressure (MIP) and the maximal expiratory pressure (MEP) to 77% and 60% predicted, respectively.[60] In a group of 21 ambulatory stable MS patients, the % predicted MEP was significantly reduced when compared with age-matched healthy controls (69.4% vs. 85.6%; $p = 0.03$). Furthermore, these patients had a greater change in the upright versus supine FVC compared with healthy controls (262 vs. 98 mL; $p = 0.001$).[61] Not surprisingly the MEP had an inverse correlation ($r = -0.47$; $p = 0.04$) with MS functional scores. These data suggest that even in ambulatory MS patients without respiratory symptoms, respiratory muscle weakness is present and should be monitored periodically (particularly MEP).

In 60 bedridden MS patients, pulmonary function studies revealed severely decreased MIP (47% predicted), severely decreased MEP (30% predicted), and vital capacity that was 80% of predicted. In those with a vital capacity below 80% predicted, the MIP and MEP were significantly lower than those with a normal vital capacity.[62] Another study of 73 wheelchair-bound MS patients demonstrated that 72.6% of patients had respiratory impairment (defined as FVC <80% predicted)[63] with a mean VC of 57.9% ± 33.5% predicted. The VC was <50% predicted in 46.6% of the patients. As in previous studies, the MEP was lower (26.9% ± 22.1% predicted) than the MIP (33.1% ± 22.7% predicted). Cough was impaired in 61.6% of the patients (mean peak cough flow of 3.14 L/s), and 37% had severe cough impairment defined as peak cough flow <27 L/s.[63] These studies suggest that respiratory impairment is often present in MS patients whether they remain ambulatory, are wheelchair bound, or bed bound. In all these studies the MEP was more affected than the MIP, and the respiratory muscle weakness directly correlated with the severity of the subject's overall neurologic function.

Smeltzer et al. developed a pulmonary dysfunction index for patients with MS and found that it correlated with MEP measurements. The score assesses the patient's assessment of cough and ability to handle secretions, the examiner's assessment of cough, and how high the patient can count on a single exhalation (Table 84-5). A subject with normal cough efficacy would have a score of 4 while an individual with the most impairment would have a score of 11.[64] As in other neuromuscular disorders the use of respiratory muscle training remains controversial. Gosselink et al. examined the effect of respiratory muscle training (e.g., three sets of 15 expiratory contractions at 60% of MEP twice daily) on respiratory muscle strength and the subject's pulmonary index score in a group of severe MS patients.[65] At 3 months there was a statistically significant improvement in MIP, and although the MEP improved the p value was 0.07 compared with control patients. The pulmonary index was statistically better at 3 months and 6 months following expiratory muscle training, but the FVC was not.[65]

A subsequent study in 17 ambulatory MS patients who underwent expiratory muscle training was able to statistically improve MEP, but this did not improve pulmonary function or markers of cough effectiveness.[66] Another study looked at effect of inspiratory muscle training performed as 3 sets of 15 repetitions per day for 10 weeks on respiratory muscle function in 37 non-ambulatory MS patients (age 60.5 ± 8.6 years). The MIP did improve from a baseline of

Data from Smeltzer SC, Skurnick JH, Troiano R, et al. Respiratory function in multiple sclerosis. Utility of clinical assessment of respiratory muscle function. Chest. 1992;101(2):479–484.

25.9 ± 16.4 cm H_2O to 30.6 ± 17.6 cm H_2O ($p < 0.05$). The MIP remained improved up to 8 weeks following the IMT training, but there was no improvement in the MEP. The investigators did not look at lung function or overall functional status.[67] Based on these data the American Academy of Neurology gives inspiratory muscle training a grade of weak evidence in treatment of patients with MS and suggests that IMT is possibly effective.[68]

Treatment of MS has traditionally included the use of immunosuppressive agents such as high-dose corticosteroids, cyclophosphamide, intravenous immunoglobulin (IVIG), and azathioprine. However other more effective and less toxic disease-modifying treatments have emerged over the last ten years, including medications such as glatiramer, mitoxantrone, interferon beta (IFN-β-1a), natalizumab, fingolimod, alemtuzumab, teriflunomide, and ocrelizumab.[69,70] The choice of therapy depends on the clinical situation and whether relapsing remitting or secondary progressive disease is being treated. Now that many disease-modifying therapies are available, the American Academy of Neurology recommends individualization of treatment regimens, which should take into consideration patient preferences, comorbidities, and potential side effects of medications when initiating or changing disease-modifying therapies.[70] Ocrelizumab, a humanized monoclonal antibody the selectively depletes CD20+ B cells, has been shown to be superior to IFN-β-1a for relapsing MS[71] and is the only drug to date that has demonstrated the ability to slow disease progression in patients with primary progressive MS.[72]

Despite the use of disease-modifying agents, acute exacerbations or remissions will occur, and it is important to educate patients and caregivers regarding these events.[70] Treatment of these acute attacks of the relapsing remitting form of the disease centers on high-dose corticosteroids.[69] In one randomized, placebo-controlled study, treatment with 10 days of high-dose oral methylprednisolone resulted in improved neurologic function, but there was no difference in the reoccurrence of future acute exacerbations.[73] More recent evidence demonstrated that 1000 mg of oral methylprednisolone for 3 days is noninferior to 3 days of 1000 mg of intravenous methylprednisolone. The investigators randomized 100 patients to oral methylprednisolone arm and 99 to intravenous methylprednisolone. The primary outcome, the proportion of patients who had improvement in functional score by day 28, was similar between the two groups (81% oral vs. 80% intravenous; treatment difference of 0.5%; 90% CI, –9.5 to 10.4).[74]

The use of IVIG has been controversial due to a lack of randomized controlled trials, but it does appear that IVIG can both delay and prevent the occurrences of acute attacks in the relapsing and remitting form of the disease in some patients.[75] Achiron et al. have shown that in patients given IVIG within the first 6 weeks of neurologic symptoms, there was a significant reduction in disease activity as measured by MRI imaging and neurologic symptoms.[76] However, there was no significant additional benefit to adding IVIG to methylprednisolone therapy, and a recent study looking at the effect of IVIG use for 27 months in secondary progressive multiple sclerosis failed to show any difference in progression of disability.[77] Although there are only case series and single-center retrospective studies to support its use, most experts suggest that plasmapheresis be used when high-dose steroids do not result in a clinical response.[69]

■ Lower Motor Neuron Lesions

Two notable lower motor neuron disorders have a significant respiratory impact and are considered below: poliomyelitis and amyotrophic lateral sclerosis.

Poliomyelitis

In the early part of the 20th century, poliomyelitis was the most common cause of lower motor neuron disease in the United States. Paralytic poliomyelitis is the most devastating respiratory presentation of poliomyelitis infection and is preceded by a period of fever and mild illness. After several days of mild fever and myalgia, symptoms disappear; then, 5 to 10 days later, fever reoccurs with signs of meningeal irritation and asymmetric flaccid paralysis. Respiratory motor nuclei may be directly involved, resulting in diaphragmatic or other respiratory muscle dysfunction. In 6% to 25% of paralytic cases, bulbar symptoms may arise, increasing the risk of upper-airway obstruction, pooling of pharyngeal secretions, and pulmonary aspiration. Moreover, the central respiratory centers can be directly affected, resulting in irregular respirations.[78]

In contrast to Guillain-Barré syndrome, sensation is intact. Tendon reflexes are significantly diminished or absent. Cerebrospinal fluid analysis shows a pleocytosis associated with mild protein elevation, and electroneuromyography shows widespread patchy denervation.

Some 15% to 30% of adults with paralyzing infection die, and treatment overall is supportive. Many patients require aggressive ventilatory and hemodynamic support during the acute phases of their illness. As temporarily damaged nerve cells regain function, recovery begins and may continue for as long 6 months. Paralysis persisting beyond that point is permanent, however, and may be associated with complaints of severe pain, which sometimes recurs years after the illness.

Some patients develop progressive muscle weakness 20 to 30 years after the initial infection. This has been termed "post-polio syndrome."[78] Symptoms vary from mild to moderate deterioration of function, with fatigue, joint pain, or weakness that may progress to muscle atrophy. The most common symptom is muscle pain (typically after exertion), which occurs in 36% to 86% of the patients. The weakness tends to progress slowly, with an average decline in muscle strength of approximately 1% per year. The pathogenesis appears to be due to dysfunction of surviving motor neurons, with slow disintegration of axonal terminals eventually leading to muscle denervation. Although respiratory complaints are common in this disorder, significant hypoventilation with elevated Pa_{CO_2} rarely occurs.[79] Respiratory failure is more common in those who required mechanical ventilation during the acute poliomyelitis phase.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a chronic, degenerative neurologic disorder characterized by death of motor neurons in the cerebral cortex and spinal cord. The result is a combination of upper and lower motor neuron dysfunction, manifested by spasticity and hyperreflexia muscle wasting, weakness, and fasciculations. It has an incidence of approximately 1 to 2 cases per 100,000 people. Males are more commonly affected than females—by a 2:1 ratio. Most cases are sporadic, but approximately 10% of cases are familial, and there is no difference in response to therapy in those with familial ALS (FALS) or sporadic cases.[80] ALS is now recognized as a multisystem disorder that can initially present as cognitive defects prior to the development of motor symptoms and is known as ALS with frontotemporal degeneration (FTLD). Additionally, some FTLD patients go on to develop motor symptoms consistent with ALS. The main pathologic finding is abnormal accumulation of insoluble proteins in the cytoplasm of motor neurons.[81] Recently it was discovered that two of these proteins are TAR DNA–binding protein 43 (TDP-43) and fused in sarcoma/translated in liposarcoma (FUS/TLS). Mutations in the genes encoding for these proteins have been found in FALS, SALS, and FTLD, but not in ALS associated with mutations in the superoxide dismutase 1 (SOD-1) gene on chromosome 21.[81] Even in FALS, genetic mutations have been discovered in only about 30% of the cases and most remain unexplained.[81]

The usual clinical presentation is progressive weakness of the distal extremities, although severe respiratory muscle weakness, particularly intercostal muscle and diaphragm weakness, has resulted in some ALS patients presenting with respiratory insufficiency as the initial symptom. Respiratory muscle impairment is more evident in the advanced stages of the disease. Abnormalities in pulmonary function are apparent, even in patients with mild extremity weakness. Progression of respiratory impairment is much faster in ALS than in other chronic neuromuscular disorders, and serial lung function studies in ALS patients show progressive reduction in FVC and MVV. In contrast to patients with other neurologic disorders, however, patients with ALS usually have a normal or slightly elevated transpulmonary pressures at FRC, and RV is usually increased and continues to rise as the disease progresses with maintenance of a normal TLC.[82] These changes are thought to be due to earlier involvement of the abdominal musculature, with preservation of intercostal and diaphragm function. Support for these physiologic findings comes from pathologic studies that show a more pronounced loss of motor neurons in the lumbosacral and lower thoracic spinal segments than in the upper and mid-thoracic regions.

The use of spirometry and respiratory muscle testing has been used to help determine the prognosis and help clinicians decide when to initiate ventilatory assistance. Investigators used the placebo arm of a clinical trial of topiramate in ALS to study the decline of FVC over 12 months in 97 patients with ALS.[83] They found that the FVC declined linearly over 12 months and that the rate of decline in FVC was an independent predictor of mortality. Those with an FVC% decline in 3 months that was greater than the median rate of decline had a mortality rate of 47% compared with 8% in those with a slower rate of decline. Forceful exhalation during the FVC maneuver can cause fatigue or bronchospasm in ALS patients, thus underestimating lung capacity.

The slow vital capacity (SVC), a slower gentle exhalation after maximal inhalation, is thought to be easier for patients with neuromuscular disease and particularly ALS. The rate of SVC decline was studied in 893 placebo-treated patients from 2 large clinical trials and an ALS trial database.[84] These data were used to assess the relationship of decline in SVC to respiratory-related events in ALS. The decline in SVC demonstrated weak but significant correlation to onset of dyspnea ($r = 0.23$; $p < 0.001$), orthopnea ($r = 0.23$; $p < 0.001$), and respiratory insufficiency ($r = 0.26$; $p < 0.001$). The investigators also created a Cox proportional hazards regression model of time to clinical events and found that if the slope of SVC decline decreased by 1.5 percentage points per months there was a 23% reduction in tracheostomy or death at 6 months.[84] The authors concluded that the rate of decline in SVC is associated with clinically meaningful events and can be a meaningful clinical outcome measure for use in in clinical trials. The sniff nasal inspiratory pressure (SNIP) test is theoretically easier than the FVC or the SVC maneuver for the ALS patient, because a tight seal around a mouthpiece is not required. A sniff is a short voluntary inspiratory maneuver, which has been shown to correlate with invasive nonvolitional tests of diaphragm strength. A SNIP <40 cm H_2O was associated with a hazard risk for death of 9.1, with a median 6-month survival of 50%. Surprisingly, in those with SNIF <40 cm H_2O, 66% had an FVC above 50%, and the hazard risk for death was 13.6 in this group.[85] When comparing the two techniques for the ability to predict 6-month mortality, the SNIP test had a sensitivity of 97% and specificity of 79% while the FVC was 58% sensitive and 96% specific.[85]

A separate study also has shown that in ALS patients without bulbar involvement SNIP was superior to both vital capacity and maximal inspiratory pressure in predicting the development of respiratory failure as defined by hypercapnia (Pa_{CO_2} >45 mm Hg) with a specificity of 85% and sensitivity of 81%.[86] In patients with significant bulbar involvement, there was no single test of respiratory muscle function that reliably predicted the development of respiratory failure.[86]

The shape of the flow-volume curve may also pinpoint the subgroup of ALS patients with greater weakness of the expiratory muscles. In patients with severe expiratory muscle weakness, the flow-volume curve near RV shows a sharp drop in flow such that the maximum expiratory curve has a concave appearance. This group of ALS patients usually has lower maximum expiratory pressures, smaller VC, reduced expiratory reserve volume, and a higher RV than do ALS patients with more-normal-appearing flow-volume curves.[82] A prospective study of 55 ALS patients demonstrated that the peak expiratory flow time increased over baseline at a rate of 4.7% per month while the decline in the FVC was only 1.2% per month. The authors concluded that the peak expiratory flow rate can be used as an earlier marker of pulmonary involvement from ALS.[39]

ALS is a progressive and uniformly fatal neuromuscular disease, and all patients will eventually develop respiratory failure, which will necessitate the discussion of mechanical ventilation (Chapters 148 and 149). Currently, guidelines from the American Academy of Neurology recommend treatment with noninvasive mechanical ventilation once the FVC is below 50% of predicted, MIP < −60 cm H_20, or SNIP <40 cm H_2O, or once orthopnea is seen.[87] Ventilation with noninvasive bilevel positive airway pressure has been shown to increase both survival and quality of life in patients with ALS, while those with orthopnea seemed to derive the most benefit.[88–91] A randomized controlled trial of noninvasive ventilation compared to standard of care in 41 patients with ALS who had orthopnea with PI_{max} <60% predicted or symptomatic daytime hypercapnia confirmed these findings. The investigators found that overall survival was prolonged in the noninvasive ventilation group (219 [75–1382] vs. 171 [1–878] days; $p = 0.006$), with the greatest benefit in those without severe bulbar symptoms.[90] There was also improved quality of life in the noninvasive ventilation group overall, but the effect was seen only in those without severe bulbar symptoms.[90]

Although noninvasive ventilation (NIV) is commonly used at night in ALS and other neuromuscular diseases, the effect NIV on sleep quality was not addressed in early NIV studies. One group of investigators admitted 24 ALS patients to the sleep lab for titration of NIV based on polysomnogram (PSG) parameters and nocturnal capnography.[92] The mean inspiratory pressure was 14 ± 2 cm H_2O, and the mean expiratory pressures were 4 ± 1 cm H_2O with a backup rate of 16 ± 2/min for those on ST mode. They found that NIV improved stage 3 and REM sleep even though overall sleep time was not increased. Furthermore, there was less nocturnal hypoxemia and less time with transcutaneous CO_2 >55 mm Hg at night compared with the baseline study. There were significant improvements in daytime sleepiness as measured by the Epworth Sleepiness Scale (8.0 [3.8–10.0] vs. 4.5 [3.0-7.3]; $p < 0.05$) and overall sleep quality as measured by the Pittsburgh Sleep Quality Index (8.5 [6.8–13.30] vs. 5.0 [3.0–8.3]; $p < 0.01$).[92]

There was interest in using diaphragm pacing via phrenic nerve stimulation in patients with ALS after initial uncontrolled studies demonstrated efficacy. However, two randomized controlled trials both were stopped early due to increased mortality in the diaphragm pacing groups.[93,94] Although the mechanism for increased mortality is unclear, the authors hypothesize that it could be due to acceleration of ALS following a surgical procedure, the combination of a natural and unnatural (paced) respiratory rhythm, or the stimulation of already damaged motor neurons leading to even more damage.

Due to weakness of both inspiratory and expiratory muscles, patients with ALS have diminished cough reflex. Impaired cough becomes even more important when airway secretions are increased during respiratory infections or in those with bulbar symptoms. One group of investigators prospectively followed 53 patients with ALS for 1 year and found that peak cough flow (PCF), peak cough flow/peak velocity time (PCF/PVT), and severity of bulbar symptoms were most predictive of ineffective cough during a respiratory infection.[95] A mechanical insufflation-exsufflation (MI-E) device can be used to augment cough in patients by providing positive airway pressure at 40 to 45 cm (insufflation) for a few seconds and then suddenly switching to 40 to 45 cm of negative pressure (exsufflation). This creates high-volume expiratory airflow that can be timed with coughing during exsufflation. MI-E increased PCF by 19% in ALS subjects with bulbar symptoms and 21% in those without bulbar symptoms.

Treatment of the other respiratory complications of ALS includes a high index of suspicion for impaired swallowing due to bulbar involvement. Difficulty in swallowing food or even saliva predisposes patients with ALS to a markedly high risk for pulmonary aspiration. Special swallowing precautions, earlier placement of enteral feeding tubes, or antisialogogues may be required.

Riluzole (an antiglutamate medication) and edaravone (a free radical scavenger of peroxyl radicals and peroxynitrite) are pharmacologic agents currently approved for use in ALS. Riluzole has been shown to induce a significant improvement in median survival from 11.8 to 14.8 months and to decrease the rate of deterioration in muscle strength in comparison with a placebo.[96,97] A randomized controlled clinical trial (RCT) with edaravone enrolled 137 patients with early ALS defined as disease duration of <2 years and FVC >80% predicted.[98] The primary outcome was change in an ALS Functional Rating Scale-Revised (ALSFRS-R), which is a 12-item questionnaire regarding functional status with higher scores indicating better function (range of score 0–48). There was a slight decrease in rate of decline in ALSFRS-R for the edaravone group compared with placebo (-5.01 ± 0.64 vs. -7.50 ± 0.66; $p = 0.0013$). The FVC declined by 15.61 percentage points in the edaravone group compared with a decline of 20.4 percentage points in the placebo group, but the difference was not statistically significant.

More recently, a RCT compared sodium phenylbutyrate-taurursodiol to placebo and found a slower functional decline on the ALSFRS-R in the medication arm—and as with other pharmaceuticals there was not a significant difference in SVC.[99] Subsequent analysis of this trial demonstrated that those in the phenylbutyrate-taurursodiol group had improved survival compared with the placebo arm (median survival, 25.0 vs. 18.5 months; HR, 0.56; CI, 0.34–0.92; $p = 0.023$).[100]

However, despite any pharmacologic interventions, ALS is a progressive and fatal neuromuscular disease, and all patients eventually develop respiratory failure and ventilatory assistance will therefore need to be considered. In those without bulbar involvement, noninvasive forms of ventilatory support are clearly indicated and will provide both a survival and quality-of-life benefit. Airway intubation may be required because of bulbar dysfunction further impairing cough and the inability to clear secretions. Long-term invasive ventilatory support is infrequently applied in ALS patients, but decisions must be made on an individual basis.

■ Disorders of Peripheral Nerves

Phrenic nerve dysfunction can be a significant cause of respiratory weakness in patients with neuromuscular diseases due to a variety of causes.

Diaphragm Paralysis

Unilateral or bilateral diaphragm paralysis following phrenic nerve injury can result from cardiac surgery, trauma, mediastinal tumors, infections of the pleural space, or forceful manipulation of the neck. Phrenic nerve injury during open-heart surgery is one of the most common causes of unilateral and bilateral diaphragm paralysis and is due either to cold exposure during cardioplegia or to mechanical stretching of the phrenic nerve during surgery. Diaphragm paralysis may also be seen with a variety of motor neuron diseases, myelopathies, neuropathies, and myopathies.

Bilateral diaphragm paralysis is characterized by a severe restrictive ventilatory impairment, with VC being frequently less than 50% of predicted in the upright position and a further reduction of 25% or more in VC in the supine position. TLC is also markedly decreased, as are FRC and static pulmonary compliance. In most patients with nontraumatic bilateral diaphragm paralysis, the most important clinical feature is orthopnea out of proportion to the severity of the underlying cardiopulmonary disease.[15]

In patients with nontraumatic bilateral diaphragm paralysis, the diaphragm usually goes unrecognized until they present with cor pulmonale or cardiorespiratory failure. A chest radiograph showing elevation of both hemidiaphragms with volume loss and/or atelectasis at the lung bases is common. The diagnosis of bilateral diaphragm paralysis should be considered when any of the following four abnormalities is present: (1) a 40% or greater reduction in VC in the supine compared to upright position; (2) fluoroscopically observed paradoxical movements of both hemidiaphragms during a "sniff" test; (3) absence of phrenic latency or phrenic nerve conduction velocity tests or lack of EMG evidence of spontaneous diaphragm activity; and (4) transdiaphragmatic pressure two standard deviations below the expected mean for normal subjects with paradoxical inward abdominal motion during maximum inspiratory efforts.[2,17,18,101]

Because, in most patients, bilateral diaphragm paralysis occurs in the context of global respiratory muscle impairment, measurements of PI_{max} and PE_{max} may be sufficient to arouse suspicion of diaphragm paralysis as a cause of the patient's complaints. With diaphragm paralysis, a marked reduction in PI_{max} with preservation of PE_{max} should be found, and in general, there is a correlation between maximum inspiratory pressures and Pdi_{SNIFF}. Reductions in Pdi_{SNIFF} to less than 30 cm H_2O are accompanied by orthopnea, a supine decrease in VC, and the presence of abdominal paradox. In most cases, the presence of severe bilateral diaphragm weakness can be diagnosed from physical exam, measurements of VC in the upright and supine positions, and PI_{max} and PE_{max}. In cases where the diagnosis is uncertain, or when definite documentation is desired, measurement of transdiaphragmatic pressures, phrenic nerve conduction times, EMG activity, transdiaphragmatic pressures during phrenic nerve stimulation, or ultrasound imaging of the diaphragm may be performed.[2] An elevation in Pa_{CO_2}, particularly in the supine position in patients with diaphragm paralysis has been reported but is not consistent.

Hemidiaphragm paralysis is more common than bilateral paralysis and is usually diagnosed from unilateral elevation of the hemidiaphragm on chest radiograph. Ultrasound of the diaphragm can be performed to confirm the diagnosis as well.[2] Most disorders reported as causing bilateral diaphragm paralysis have also been reported as causes of unilateral paralysis (e.g., cervical spondylosis, spine cord injury, poliomyelitis, and muscular dystrophy). Other, more specific causes of unilateral diaphragm paralysis are pneumonia, trauma from central vein cannulation, and viral infections of the cervical nerve roots.

Patient complaints and physical examination abnormalities in unilateral diaphragm paralysis are usually the same as with bilateral diaphragm paralysis but are less striking. Orthopnea is a frequent complaint, but it is less dramatic than in patients with bilateral paralysis. Moreover, physical examination findings are nonspecific but occasionally may show paradoxical inward motion of the paralyzed hemidiaphragm with a reduction in breath sounds at the affected lung base and an increase in dullness on percussion. The alveolar arterial oxygen gradient may be increased with mild hypoxemia due to the reduction in ventilation and perfusion of the lower lobe on the affected side.

Tests of diaphragm function are intermediate between those in patients with bilateral diaphragm paralysis and normal predicted values. VC in the upright posture may be reduced to 74% to 81% of predicted, with a fall in VC also present in the supine compared to erect position, but of lesser magnitude than in patients with bilateral diaphragm paralysis. In patients with right hemidiaphragm paralysis, the fall in VC may be almost twice as great (19% vs. 10%) in comparison with left-sided paralysis, owing to the weight of the liver further encroaching on lung volume. Maximum inspiratory mouth pressures are frequently reduced to approximately 50% to 62% of normal. Similar reductions are found in maximum P_{di} measured during maximum static voluntary efforts and during maximum sniff.

Treatment of patients with bilateral diaphragm paralysis is similar to that of other patients with chronic neuromuscular diseases. Eliminating nocturnal hypoventilation, especially during REM sleep, is warranted, and the implementation of noninvasive ventilation, especially positive-pressure ventilation, may be indicated. In some cases of symptomatic unilateral hemidiaphragm elevation, surgical plication of the affected hemidiaphragm may relieve symptoms and improve FVC and transdiaphragmatic pressure. A series of 22 patients who underwent diaphragmatic plication were followed for an average of 4.9 years, and the investigators found that the percent decline in FVC from seated to supine position improved from 34% (range, 10%–47%) preoperatively to 9% (range, 0%–21%) postoperatively ($p = 0.004$). There also was an improvement in the transitional dyspnea index (TDI) postoperatively, but the TDI did not correlate with the improvement in spirometry.[102] Surgical plication is achieved by placing a series of 6 to 8 U-shaped sutures in the diaphragm, which results in the diaphragm becoming fixed and immovable. This prevents excursion of the diaphragm into the thoracic cavity during inspiration and permits the accessory muscles of respiration to generate negative intrathoracic pressure.

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) precipitates respiratory failure more often than any other peripheral neuropathy. It is an acute idiopathic polyneuritis with an annual incidence of 0.89 to 1.99 cases per 100,000 people.[103] It usually presents as paresthesia and ascending paralysis of the lower extremities with absent deep-tendon reflexes in a symmetrical distribution. Objective findings of sensory loss are variable, and the degree of motor weakness can range from mild paresis to complete paralysis. Maximum weakness of the lower extremities occurs within 2 weeks in 50% of cases, and 90% of cases reach their nadir in weakness by 4 weeks. After the nadir is reached, patients remain at that level for an additional 1 to 4 weeks before recovery begins. Facial, ocular, and oropharyngeal muscles may be impaired as well as the respiratory muscles. Respiratory muscle weakness and, specifically, severe diaphragm weakness may be found in patients with GBS.[103]

The distribution of muscle weakness between respiratory and non-respiratory muscles is not uniform in GBS, and peripheral muscle strength does not correlate with the presence or absence of respiratory muscle weakness. However, ventilatory failure correlates with diaphragmatic weakness.

The impairment on respiratory tests in GBS is similar to that for other generalized neuromuscular diseases. A decline in FVC and maximum inspiratory and expiratory mouth pressures, impairment in nocturnal gas exchange during REM sleep, and the onset of hypercapnia detected by arterial blood gas analysis have all been reported in symptomatic GBS patients. An FVC of 15 cc/kg is a sign of imminent respiratory failure in GBS.[103,104]

Hypercapnia is a late sign of respiratory failure, with the average Pa_{CO_2} at the time of intubation 43 mm Hg when FVC is less than 12 cc/kg.

Respiratory treatment of GBS patients is mainly supportive. Since bulbar involvement, leading to swallowing dysfunction, increases the propensity for pulmonary aspiration, special precautions for feeding and control of upper-airway secretions may be required. Primarily because of bulbar dysfunction in those with respiratory failure, noninvasive ventilation has not been used outside of a few case reports. Individual cases without bulbar dysfunction merit special consideration, and the use of noninvasive ventilation may be appropriate. Approximately 20% to 30% of GBS patients will require mechanical ventilation. Airway intubation and mechanical ventilation should be initiated when one major criterion or two minor criteria are present (Table 84-6).[103] Earlier intubation and assisted ventilation may be indicated to avoid complications that arise from progressive respiratory failure, overwhelming pulmonary infections, or both. When indicated, intubation and mechanical ventilation should be initiated early because emergent intubations have been associated with worse outcomes. It is well established that mechanical ventilation is indicated when the vital capacity falls below 15 cc/kg. However, it would be ideal to predict the need for mechanical ventilation at an earlier time.

A Dutch group of investigators demonstrated that the most important factors in predicting respiratory failure in the first week of hospitalization were Medical Research Council (MRC) sum score (a muscle strength score), days between onset of weakness and hospitalization, and the presence of facial and/or bulbar weakness at hospitalization.[105] Based on their model the Erasmus GBS Respiratory Insufficiency Score (EGRIS) was made and is shown

TABLE 84-6 Criteria for Airway Intubation and Mechanical Ventilation in Guillain–Barré Syndrome

Major Criteria	Minor Criteria
Hypercarbia (Pa_{CO_2} ≥48 mm Hg)	Ineffective cough
Hypoxemia (Pa_{O_2} ≤56 mm Hg)	Impaired swallowing
Vital capacity <15 cc/kg	Atelectasis

TABLE 84-7 Erasmus GBS Respiratory Insufficiency Score (EGRIS) for Predicting Respiratory Failure in the First 7 Days of Hospitalization

Measure	Categories	Score
Days between onset of weakness and hospitalization	>7 days	0
	4–7 days	1
	≤ 3 days	2
Facial and/or bulbar weakness on hospitalization	Absent	0
	Present	1
MRC sum score at hospitalization	60–51	0
	50–41	1
	40–31	2
	30–21	3
	≤ 20	4
EGRIS	**Risk of Intubation (%)**	
Low (0–2)	4	
Intermediate (3–4)	24	
High (5–7)	65	

GBS, Guillain-Barré syndrome; MRC, medical research council.

in Table 84-7. Patients at highest risk for intubation (EGRIS 5–7) should be admitted to the ICU for close observation and timely intubation if required. Evaluation for discontinuation of mechanical ventilation is not different in individuals with GBS, but if dysautonomia is present at the time of extubation then reintubation rates are exceedingly high (73% vs. 26.7%; $p = 0.008$)[106] while an improvement of >4 mL/kg in vital capacity was associated with a 90% positive predictive value for extubation.[106] Aggressive pulmonary toilet, including repeated bronchoscopy, may be needed to decrease atelectasis and the incidence of nosocomial pneumonia.

In a multicenter trial, plasmapheresis (total of four treatments), using either albumin or fresh frozen plasma as replacement fluids, produced short-term benefits in earlier motor recovery, ambulation, and reduction in number of patients who required assisted ventilation, and shortened the duration of mechanical ventilation.[107] A subsequent study from the same group showed that two plasmapheresis treatments were better than none in mild disease, but four were better than two in moderate and severe disease. Greater than four treatments were not beneficial even in severe disease. Intravenous immunoglobulin (IVIG), given within 2 weeks after the onset of GBS, may also be effective therapy.[108] IVIG has been compared to plasmapheresis; recovery was as effective as plasmapheresis and may have been slightly better. In a study of 150 patients with GBS, 53% of the group treated with IVIG had an improvement of one grade (on a seven-point scale) in muscle strength compared with 34% of those treated with plasmapheresis after 4 weeks of therapy.[109] Currently, there is no evidence from randomized controlled trials to support the use of corticosteroids in the treatment of GBS.

Critical Illness Polyneuropathy

Critical illness polyneuropathy (CIP) was initially described in five patients that had survived sepsis and multisystem organ failure, and the entity is now recognized as a serious complication of critical illness that contributes significantly to morbidity and mortality.[110,111]

The disease is common, with as many as 68% of patients with sepsis and multisystem organ failure requiring mechanical ventilation having evidence of CIP on electromyography/nerve conduction studies. Patients affected by this disorder typically exhibit varying degrees of musculoskeletal weakness, which ranges from mild weakness to near total paralysis with hyporeflexive deep-tendon reflexes. Unfortunately, physical exam is unreliable as the sole means of diagnosis, and electromyography with nerve conduction studies (EMG/NCS) are required to confirm the diagnosis. EMG studies in these patients show a reduction in the amplitude of the compound muscle action potential without significant prolongation of stimulus latency, suggesting primarily axonal nerve damage rather than a demyelinating process.

Recognition of CIP is important because the disease affects patient management and the prognosis of recovery from the critical illness. Patients who develop CIP tend to require a longer period of mechanical ventilation and longer hospital stays compared to those without CIP. Garnacho-Montero et al. found in a group of patients with sepsis and prolonged mechanical ventilation that those with CIP required 34 days of mechanical ventilation versus only 14 days for those without CIP. Additionally, the weakness associated with CIP results in an extended rehabilitation period, and there is evidence of persistent neuropathy on EMG/NCS as long as 5 years after discharge from the intensive care unit. Patients who develop CIP appear to have a higher mortality, with one study showing a 3.5-fold increase in ICU mortality, and another with significantly higher in-hospital mortality.[112]

Although the exact mechanism for axonal damage in this syndrome is unknown, several risk factors for the development of CIP have been described. Two of the most important risk factors are the presence of the systemic inflammatory response syndrome (SIRS) and the APACHE III score. One study looked at 98 patients prospectively and found that 72% of patients with SIRS and an APACHE III score above 85 will develop CIP. Multivariate analysis of associated risk factors from another study found that hyperosmolality, parenteral nutrition, the use of neuromuscular blocking agents, and neurologic failure (GCS <10) were associated with an increased risk of developing CIP.[113] Exactly how these risk factors lead to the development of CIP is not known, but possibilities include nerve toxins released during episodes of multisystem organ failure, antibiotics impairing neuromuscular transmission, protracted use of neuromuscular blocking agents, and hyperglycemia causing nerve ischemia by endovascular shunting.

Because no specific therapy for CIP exists, treatment is purely supportive and includes aggressive rehabilitation, nutrition support, and treatment of any medical complications. It should be emphasized to both patient and family that recovery may be prolonged (as long as 5 years).[114]

■ Disorders of the Neuromuscular Junction

Below we discuss important disorders of the neuromuscular junction that may have profound respiratory effects: myasthenia gravis, Eaton-Lambert syndrome, and botulism.

Myasthenia Gravis

Myasthenia gravis is an autoimmune disorder characterized by impaired transmission of neural impulses across the neuromuscular junction due to the production of antibodies directed against the acetylcholine receptor. The prevalence of myasthenia gravis is estimated to be approximately 1 in 10,000 people, with 2-to-1 female-to-male predominance. It occurs more often in younger than older adults. The typical myasthenic patient presents with fluctuating muscular weakness, with improvement after rest and the administration of anticholinesterase agents (e.g., edrophonium chloride). Ocular, facial, and neck muscles are commonly affected, but patients who have the most severe respiratory involvement have either acute fulminating or late severe classifications of myasthenia gravis.

In 17 patients with moderate, generalized myasthenia gravis, pulmonary function studies before the administration of edrophonium chloride reveal a mild reduction in VC and moderate reductions in both maximum inspiratory (approximately 54% of predicted) and expiratory (reduced to approximately 52% of predicted) mouth pressures.[115] Because of increased lung recoil pressure, normal or supranormal values of maximal expiratory flow are seen in relation to lung recoil pressure or absolute lung volume. Although upper airway obstruction due to bulbar muscle involvement is theoretically possible, it has rarely been reported. However, Putman and Wise examined flow–volume loops in myasthenia gravis patients that were adequate for interpretation. They found that in 12 patients with myasthenia gravis with reproducible flow–volume loops, 7 had either a variable extrathoracic or fixed upper airway obstruction suggesting that upper airway obstruction maybe more common than previously thought.[116]

Acute respiratory failure usually occurs in the setting of a myasthenic crisis or cholinergic crisis or as the initial presentation of the disease. A myasthenic crisis refers to worsening of the basic underlying disease, usually precipitated by decreased anticholinesterase medication, surgery, or administration of neuromuscular blocking medication. Clinical parameters useful in predicting the development of postoperative respiratory failure include the severity of the disease (e.g., acute fulminating or late severe categories of myasthenia gravis), a low preoperative VC, and bulbar symptoms.[117] The most common complications of myasthenic crisis are respiratory failure and recurrent pneumonias due to aspiration from bulbar involvement and impaired cough. The mean duration of mechanical ventilation in myasthenia gravis in a series of 22 patients was 8 days, with 6 patients (32%) requiring tracheostomy for prolonged mechanical ventilation. Of the 22 patients, 21 survived and were totally weaned from ventilatory support over 1 to 32 days.[118] Noninvasive bilevel positive-pressure (BiPAP) ventilation is a viable option to treat respiratory failure during a myasthenic crisis until effective therapy is delivered. BiPAP was used in a series of 11 myasthenic crisis events in 9 patients. The mean pressures used were 13/5 cm H_2O, and endotracheal intubation was avoided in all but 4 instances. The only predictor for failure of BiPAP was a Pa_{CO_2} above 50 mm Hg.[119]

A subsequent study in 24 patients treated with BiPAP (mean pressure 14/6 mm Hg) had similar findings in that 58% of myasthenia crisis patients avoided intubation, and the best predictor of BiPAP failure was a Pa_{CO_2} >45 mm Hg. Although there was no difference in mortality, those treated with BiPAP had a shorter ICU length of stay (7 vs. 13 days; $p = 0.002$).[120] These data suggest that the use of early noninvasive ventilation prior to the development of severe hypercapnia can reduce intubation rates and ICU length of stay.

The treatment of myasthenia gravis includes anticholinesterase agents, high-dose corticosteroids, thymectomy, and plasmapheresis in patients refractory to steroid or immunosuppressive therapy. Anticholinesterase agents are the first line of treatment. Most patients improve significantly with anticholinesterase agents, but only a few regain normal function. Remissions can be induced in up to 80% of patients with the use of corticosteroids. However, corticosteroids may cause temporary worsening of muscle weakness, usually on the sixth to tenth day of therapy, and close observation for signs of respiratory insufficiency is advisable.[117] Other immunosuppressive agents (e.g., cyclosporine and azathioprine) may be useful with or without concomitant corticosteroids.

In retrospective studies, thymectomy improves survival and relieves clinical symptoms, even in the absence of thymoma. In patients with thymoma, thymectomy is also indicated because the risk for malignant transformation is high in patients less than 55 years of age. In up to 80 percent of myasthenia gravis patients without thymoma, clinical improvement after thymectomy occurs during prolonged follow-up.

Plasmapheresis and the use of intravenous immunoglobulin (IVIG) produce a temporary reduction in acetylcholine receptor antibody level and may be helpful in patients with respiratory failure not responding to anticholinesterase and immunosuppressive agents. Plasmapheresis and IVIG have been compared and both are equally efficacious. However, IVIG was associated with less severe adverse reactions and therefore is the preferred initial agent in the treatment of myasthenic crisis.

Eaton-Lambert Syndrome

Eaton-Lambert syndrome is a rare myasthenia disorder resulting from a reduction in neurotransmitter release from presynaptic terminals that develops in association with tumors (especially small-cell lung carcinoma). Although patients may respond weakly to administration of edrophonium chloride, the disease is differentiated from myasthenia gravis by the predominant involvement of limb and girdle muscles compared to the ocular and bulbar muscle involvement in myasthenia gravis. Respiratory muscle weakness is often detected on pulmonary function tests, but respiratory failure is infrequent.

Botulism

Botulism is a rare disorder caused by the *Clostridium botulinum* toxin. It occurs as a result of eating improperly cooked food, wound contamination by the organism, or, especially in infants, the absorption of toxin from the GI tract. There are eight types of toxins, although human diseases are usually caused by type A, B, or E.

Botulinum toxin binds to the calcium channel in presynaptic terminals, impairing neuromuscular transmission of acetylcholine. GI symptoms predominate early in the disease, followed by neurologic impairment, including descending paralysis of the neck, trunk, and limb muscles. Weakness of the respiratory muscles requiring mechanical ventilation is frequent, especially with botulinum type A toxins. Spirometry usually reveals a restrictive ventilatory defect, and recovery from respiratory muscle weakness may take months, often requiring prolonged mechanical ventilation. The average duration of ventilatory support for type A poisoning is 58 days, in contrast to 26 days for type B botulism. Exertional dyspnea and poor exercise tolerance may persist, even with normal lung function.

■ Muscular Dystrophies and Myopathies

Respiratory function may be significantly affected by a variety of inherited muscle disorders and acquired myopathies (Table 84-8). The inherited muscular dystrophies refer to a heterogeneous group of progressive, degenerative, hereditary skeletal muscle diseases that cause severe muscle weakness, eventually resulting in repeated pneumonias, respiratory failure, and, in some cases, death. Respiratory failure, often accompanied by pneumonia, contributes to death in more than 75% of patients with Duchenne muscular dystrophy.

Duchenne Muscular Dystrophy

Duchenne muscular dystrophy (DMD) is the best characterized of these heredofamilial muscle diseases. This disease is transmitted by an X-linked recessive gene, although approximately one-third of cases arise from spontaneous mutation. The disease is due to the mutation of the gene for skeletal protein dystrophin, a

TABLE 84-8 Myopathies Likely to Produce Respiratory Abnormalities

Inherited Myopathies	Acquired Myopathies

Mitochondrial myopathies	

subsarcolemmal protein believed to play a major role in providing structural integrity in the muscle cell surface membrane. The mutation of the dystrophin gene commonly occurs in one of the 79 exons in the gene, which leads to a reading frame disruption resulting in the lack of dystrophin expression.[121] Lack of dystrophin leads to a weaker cell membrane that becomes further impaired with muscle contraction. Muscle inflammation, necrosis, and fibrosis subsequently lead to severe atrophy and loss of function. Approximately 30% to 40% of the normal amount of dystrophin must be expressed in order to prevent major myopathic symptoms. The diagnosis is confirmed by demonstrating mutation of the dystrophin gene in DNA from peripheral leukocytes, or an absence or abnormality in dystrophin in muscle biopsy samples.

Symptoms usually present in early childhood. Gait disturbances and delayed motor development are common manifestations, with proximal weakness resulting in an exaggerated lumbar lordosis. Most patients are wheelchair bound by the age of 12 to 15 years, with death occurring around the age of 20 years as a result of progressive respiratory failure and pneumonia. Kyphoscoliosis commonly develops due to severe muscle weakness and further contributes to a restrictive ventilatory deficit. Pulmonary symptoms are often minimal early on, despite significant weakness of the respiratory muscles.

Maximum inspiratory pressure is reduced at all lung volumes in patients with DMD and declines with time. FVC increases with growth during the first decade and may mask early respiratory muscle dysfunction before it plateaus and progressively decreases about 5% to 6% per year after 12 years of age[122] (Fig. 84-12). Reductions in maximum inspiratory pressure, therefore, occur early in the clinical course of DMD and may precede the reduction observed in VC. In a series of 58 DMD patients, the median decline in FVC was 0.18 L (0.04–0.74) per year; and once the FVC fell below 1 L the median survival was 3.1 years with a 5-year survival of 8%.[123]

A more contemporary cohort of 60 DMD patients aged 5 to 24 years had 131 visits with spirometry. Investigators confirmed that the raw peak FVC will occur in teenage years and then precipitously drop, but when data are expressed as % predicted there is a linear decline with age (Fig. 84-13). Peak expiratory flow had a very similar pattern.[124] Inspiratory muscle weakness does not necessarily parallel the development of expiratory muscle weakness. Maximum expiratory mouth pressures are substantially lower than maximum inspiratory mouth pressures, possibly leading to a marked decrease in the effectiveness of cough.

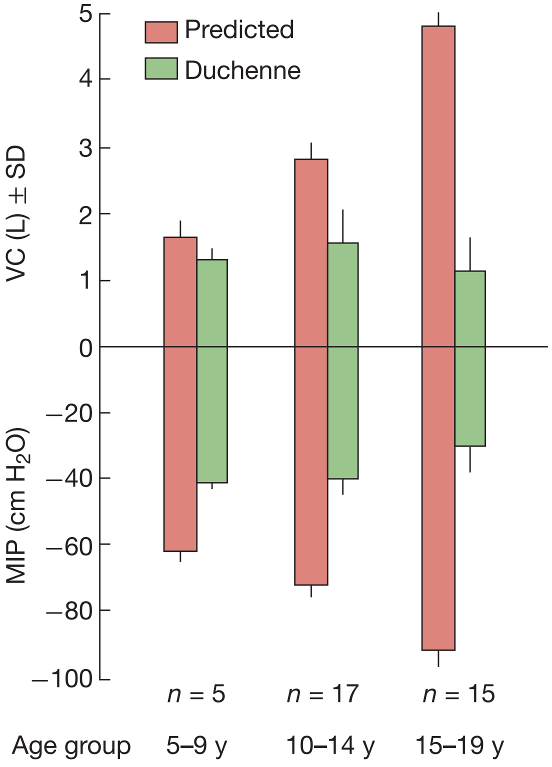

Figure 84-12 Mean vital capacity (VC) and maximum static inspiratory pressures (MIP) in 37 DMD patients in three age groups *(shaded bars)* in comparison to normal predicted values *(unshaded bars)*. MIP decreases gradually as DMD progresses, despite body growth, whereas VC increases until patients reach their early teens. *(Data from Smith PE, Calverley PM, Edwards RH, et al. Practical problems in the respiratory care of patients with muscular dystrophy. N Engl J Med. 1987;316(19):1197–1205.)*

FVC should be measured annually in patients who are able to ambulate and every 6 months in nonambulatory DMD patients. Additionally, peak cough flow, MIP, MEP, and pulse oximetry should be measured every 6 months in nonambulatory patients. Additionally, end-tidal CO_2 or transcutaneous partial pressure of carbon dioxide in blood should be measured every 6 months or any time the pulse oximetry is <95% on room air.[125]

Despite severe and progressive muscle weakness, hypercapnia is uncommon in patients with DMD in the absence of pulmonary infections. The absence of hypercapnia despite severe muscle weakness is believed to be due to relative preservation of diaphragm function until very late in the illness. Once hypercapnia occurs, however, the courses is rapidly progressive, and mean survival is approximately 10 months.

Since ventilation is heavily dependent on diaphragmatic function in DMD patients, severe nocturnal hypoventilation may occur during REM sleep, when activity of chest wall and neck muscles is markedly attenuated and has been documented in DMD patients with normal daytime gas exchange. The American Thoracic Society has recommended that an annual sleep study be performed when the patient becomes nonambulatory unless symptoms of nocturnal hypoventilation are present.[126] Sleep-related hypoxemia may contribute to respiratory insufficiency and the development of cor pulmonale.

Management of patients with DMD is mainly supportive. Ambulation should be maintained and encouraged as long as possible to retard the development of scoliosis. Surgical correction may attenuate the scoliotic contribution to the fall in VC and improve

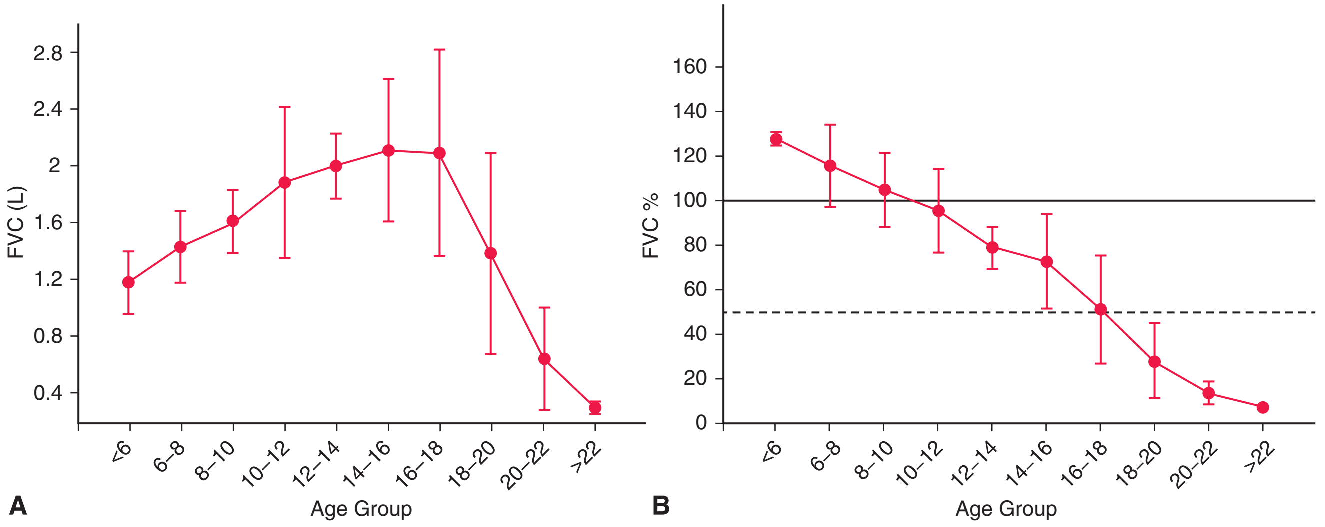

Figure 84-13 Prospectively collected FVC data in 60 children with DMD (median age, 10.3 years; range, 5–24). **A.** FVC in liters increases linearly until about age 10, then plateaus until about age 18, after which there is a precipitous decline. **B.** FVC percent predicted declined nearly linearly from the 6- to 8-year-old cohort through the 20- to 22-year-old cohort. *(Data from Mayer OH, Finkel RS, Rummey C, et al. Characterization of pulmonary function in Duchenne Muscular Dystrophy. Pediatr Pulmonol. 2015;50(5):487–494.)*

patient morale and quality of life overall. While the decline in FVC will continue postoperatively, it may be slowed somewhat. In a group of 56 DMD patients who underwent posterior spinal fusion for scoliosis, the decline in FVC decreased from 4% per year preoperatively to 1.75% per year postoperatively ($p < 0.0001$).[127]

General physiotherapy may be helpful in preventing contractures. Maintenance of proper nutrition, with an emphasis on weight control, is important. Patients with DMD have a propensity to become overweight through a combination of inactivity, reduced energy requirements, medications, and a misguided desire to improve muscle bulk by overeating. Some authors have emphasized a high-protein (more than 80 g protein daily), low-calorie diet, aiming to achieve a body weight somewhat lower than the ideal weight in patients of a similar height and normal muscle mass.

Inspiratory muscle training (IMT) has been examined as a tool to prevent further decrease in respiratory muscle function in those with DMD, but its routine use remains controversial. Because there is loss of the protective mechanism of nitric oxide release in children with DMD, IMT could potentially be detrimental. Koessler et al. studied the effect of 2 years of IMT on a group of 27 patients with neuromuscular disease (18 DMD and 9 spinal atrophy) and showed a clear increase in PI_{max} and maximum voluntary ventilation (MVV). There was a plateau reached after 10 months of training.[128] Because there is potential for harm and no long-term studies support its use, ATS guidelines do not suggest the use of routine IMT in this group of patients.[126]

Maintenance of cough and adequate airway clearance is extremely important in attempting to prevent atelectasis and pneumonia in this patient population. A PE_{max} of at least 60 cm H_2O has been shown to be adequate to generate an effective cough in patients with DMD, while a drop below 45 cm H_2O has been associated with ineffective cough.[126,129] Once an ineffective cough is recognized there are multiple treatment modalities. The most studied technique is the use of a manual insufflator-exsufflator, which stimulates cough by providing a positive-pressure breath immediately followed by a negative-pressure exsufflation. The technique can be used on patients with or without a tracheotomy and is generally well tolerated. It has been shown to be effective in generating cough and clearing airways in children with DMD, especially once scoliosis has developed.[126]

As FVC decreases in DMD, patients begin to develop chest wall noncompliance and atelectasis, and lung volumes decline. Guidelines recommend lung volume recruitment utilizing either a self-inflating manual ventilation bag or mechanical insufflation-exsufflation devices to provide deep lung inflation once or twice daily.[125]

Respiratory tract infections are a serious complication in DMD patients and must be treated aggressively with physiotherapy, postural drainage, assisted cough techniques, and appropriate antibiotics. All patients, regardless of cough status, should receive vaccination against pneumococcal pneumonia and influenza.

In some patients, assisted ventilation is required once respiratory insufficiency or symptoms of sleep-related breathing disorders are present. Other indications include FVC <50% predicted, MIP <60 cm H_2O, awake baseline saturation <95%, or Pa_{CO_2} >45 mm Hg. Intermittent noninvasive positive-pressure ventilation (NPPV) prolongs survival, improves quality of life, and may attenuate the decline in FVC and MVV. Longer-term follow-up of DMD patients treated with noninvasive ventilation demonstrates that pulmonary function continues to deteriorate 3 to 4 years after the initiation of noninvasive ventilation, with patients requiring longer periods of ventilation and/or transition to tracheostomy with positive-pressure ventilation.[130] Once patients require the use of NPPV, the pressure should be titrated in the sleep laboratory to eliminate nocturnal apneas and hypopneas. Generally, bilevel noninvasive positive airway pressure with a backup rate should be used in those with significant daytime or nocturnal hypoventilation, and CPAP should be used primarily in those with obstructive sleep apnea without evidence of hypoventilation.[125]

There is evidence to suggest that prednisone treatment is beneficial. In a randomized, double-blind, controlled 6-month trial of prednisone in 103 boys with DMD, patients were assigned to low-dose prednisone (0.75 mg/kg per day), high-dose prednisone (1.5 mg/kg per day), or placebo. Both prednisone groups showed significant improvements in muscle strength, functional scores, and FVC at 6 months compared with placebo, but there was no difference between low- or high-dose prednisone.[131] A subsequent study found that muscle strength was greater in DMD patients taking 0.75 m/kg compared to 0.3 mg/kg of prednisone for 6 months.[132] The effect of steroid therapy on respiratory muscle function has been less clear, but a prospective cohort study involving 440 patients at 20 centers found that those on steroids for >1 year had a delay in progression to milestone events such as the age at loss of ambulation, which was

13.40 ± 0.29 years versus 10.00 ± 0.29 years in those on steroids for less than 1 month ($p < 0.001$). Age at loss of ambulation was found to predict future age at progression to FVC <1 L, suggesting that a delay in the loss of ambulation can lead to better lung function. The authors also found that those on steroids for >1 year had improved survival compared to those on steroids <1 month over a 10-year time period (9% vs. 19%; $p = 0.0501$).[133] An earlier case-control study found that steroid therapy for a mean duration of 8.2 years resulted in improved FVC, MIP, MEP, peak cough flow, and FVC compared with those not treated with prednisone.[134]

Deflazacort is a heterocyclic glucocorticoid prodrug with both anti-inflammatory and immunosuppressant effects. In a multicenter, placebo-controlled, phase 3 clinical trial in 196 children with DMD, deflazacort was compared to prednisone or placebo for 12 weeks. Even as early as 12 weeks, deflazacort led to greater improvement in muscle strength compared with placebo, and at 52 weeks muscle strength was significantly improved in the deflazacort group compared with the prednisone group.[135] In addition, there was less weight gain in those treated with deflazacort compared to prednisone (5.05 vs. 8.45 kg; $p < 0.0001$). A meta-analysis of the placebo arms from two large DMD trials compared disease progression in those on deflazacort and those on prednisone. They found that those treated with deflazacort had a lower decline in their 6-min walk distance by 28.3 m (95% CI, 5.7–50.9; $p = 0.01$) at 48 weeks.[136] Based on these data expert panels have recommended that corticosteroid therapy be used in DMD patients prior to any substantial decline. Guidelines recommend either prednisone (0.75 mg/kg/day) or deflazacort (0.9 mg/kg/day) but leave the choice of therapy to the clinician.[125]

While corticosteroid therapy may improve muscle strength, functional status, and lung function, it clearly is not a cure for DMD, and most experts believe that gene therapy will be applicable to DMD in the future as a potential cure for the disease. Traditional gene therapy is limited in DMD by the large amount of skeletal muscle, the large size of the dysmorphin gene, and patient immunity against viral vectors.[137] A more recent method of gene therapy known as exon skipping is an attractive approach because some DMD mutations result in mRNA, which causes a premature stop in translation of the dystrophin protein.

Small oligonucleotides known as phosphorodiamidate morpholino oligomers (PMOs) can be developed to bind exons and block them from being incorporated into mRNA, which allows for translation of a truncated dystrophin protein resulting in some function of the native protein.[138] Eteplirsen is a PMO that binds to exon 51 of dystrophin pre-mRNA that has been demonstrated to increase the percentage of dystrophin-positive fibers in skeletal muscle biopsy and improve 6-min walk distance by 67.3 m compared with placebo ($p < 0.0001$).[139] The investigators found that the percentage of fibers positive for dystrophin in skeletal muscle increased more with time on drug rather than in a dose-dependent manner.[139] A pooled analysis compared three eteplirsen arms to a control group with the same exon 51 mutation and found that the decline in FVC percentage in the 3 different studies (−2.79, −3.66, and −3.79%) was significantly slower compared with the control (−6.00%) over a period of 2 to 4 years.[140] Since mutations in exon 51 account for only 13% of patients with DMD, other PMOs are being developed. Golodirsen is a PMO targeting exon 53 and also has been shown to increase dystrophin production in patients with DMD.[141] PMO cocktails that target multiple exons (exons 45–55) are in development and may be able to treat as many as 65% of DMD patients with in-frame and out-of-frame mutations.[142]

Despite recent pharmacologic advances, DMD remains a relentlessly progressive disease that eventually will lead to respiratory failure requiring invasive mechanical ventilation (Chapter 148). End-of-life care and plans for the use of invasive mechanical ventilation should be discussed with the family and the patient well in advance, if at all possible. While the institution of mechanical ventilation has been shown to prolong life in the appropriate setting, little is known on the effect on quality of life, and decisions must be made on an individual basis.

TABLE 84-9 Clinical Differences Between Myotonic Dystrophy 1 and 2

	Myotonic Dystrophy 1	Myotonic Dystrophy 2
Age of onset	Typically younger age	30–40
Family history	Subsequent generations worse (anticipation)	No anticipation
General appearance	Balding forehead, temporal wasting, ptosis, frequent bulbar symptoms	Rare bulbar symptoms
Muscle	Distal muscle weakness and atrophy, mytotonia of handgrip and tongue	Proximal and axial muscle weakness and atrophy, mild proximal myotonia, myalgias common
Sleep disturbances	Central and obstructive sleep apnea	Central sleep apnea
Central nervous system	Daytime sleepiness ubiquitous, concentration problems	Daytime sleepiness common, frequent hearing impairment

Myotonic Dystrophy

Myotonic dystrophy is the most common form of hereditary muscular dystrophy in adults, with an estimated incidence of 1 in 2500 people. It is now recognized that there are two forms of myotonic dystrophy (Table 84-9). Myotonic dystrophies are progressive autosomal dominant diseases caused by an abnormal expansion of an unstable nucleotide repeat located in the noncoding region of the DMPK gene for type 1 and CNBP in type 2 myotonic dystrophy.[143] Increased number of repeats present in type 1 disease correlates with increased severity of disease and earlier onset. The repeats in type 1 myotonic dystrophy increase in number with subsequent generations (called anticipation) which results in earlier onset and more severe phenotype in subsequent generations.[143] Anticipation has not been reported to occur in type 2 myotonic dystrophy. Type 1 leads to weakness in distal muscle groups, facial muscles, and ankle dorsiflexors, while type 2 myotonic dystrophy typically exhibits proximal muscle weakness with muscle pain being a common feature. Median survival has been reported to be 53.2 years, and the most common causes of death were respiratory related (43%), cardiovascular cause (especially arrhythmias) (11%), and malignancies (11%).[144] Symptoms usually present during adolescence and in early adulthood, although the syndrome may be recognized as early as infancy.[145]

Respiratory muscle weakness is common and can be severe, despite mild limb muscle weakness. Myotonia (delayed muscle relaxation) of the respiratory muscles contributes to an increased work of breathing by increasing inspiratory impedance. Studies have suggested that the presence of a chaotic breathing pattern may explain the higher prevalence of chronic hypercapnia in patients with myotonic dystrophy than in patients with other forms of muscular dystrophy. Support for these findings came from studies that showed abnormal ventilatory responses to hypercapnic challenges in patients with myotonic dystrophy. However, studies that have used mouth occlusion pressures ($P_{0.1}$) have revealed normal or supranormal responses in $P_{0.1}$ in patients with myotonic dystrophy compared with controls.[146] These data seem to suggest that prior studies showing hypercapnia in patients with myotonic dystrophy underestimated the severity of respiratory muscle weakness by itself as a limitation in the ability to mount a normal ventilatory response. The chaotic breathing pattern observed in some patients with myotonic dystrophy has been suggested to be related to disordered afferent information from diseased muscle spindles.

As in other neuromuscular diseases affecting the lung, regular testing to include measurement of FVC and MIP/MEP, and cough peak flow, is recommended at 6-month intervals.[147] The guidelines stress all patients should be screened for sleep-disordered breathing with overnight polysomnography at least once (particularly those with MIP <60 cm H_2O or FVC $<50\%$ predicted) and then have recurrent overnight pulse oximetry/transcutaneous capnometry every 6 months or repeat polysomnography as indicated. Daytime blood gas analysis is necessary, especially in the setting of respiratory muscle weakness to screen for daytime hypercapnia ($Pa_{CO_2} >45$ mm Hg).

Patients with myotonic dystrophy are particularly susceptible to development of respiratory failure with general anesthesia and sedatives, and postoperative respiratory monitoring is essential if surgery or the use of these agents is required. Extubation should be done in a recovery room or intensive care unit due to side effects of anesthesia in DM1. Pharyngeal and laryngeal dysfunction increases the risk of aspiration, and patients should be referred to specialists in dysphagia evaluation if there is suspicion as suggested by cough associated with eating, drooling, aspiration, or dysphonia.[147] Sleep-related breathing disturbances are common and may include both central and obstructive forms of sleep apnea. Nocturnal positive-pressure ventilation is indicated when FVC is $<50\%$ predicted, sleep-disordered breathing is present on polysomnography, or daytime hypercapnia occurs.[147]

Facioscapulohumeral Dystrophy

Other inherited adult muscular dystrophies are facioscapulohumeral dystrophy (FSH) and limb-girdle dystrophy. FSH is an autosomal dominant dystrophy that primarily affects muscles of the face and the proximal portion of the upper extremities. FVC is significantly reduced in patients with FSH, although facial weakness complicates spirometric assessment. In 20% of patients with FSH, the disease affects pelvic girdle and trunk muscles, sometimes impairing respiratory function.

Limb-Girdle Dystrophy

Limb-girdle dystrophy is a heterogeneous group of autosomal dominant recessive disorders. The disease usually becomes evident in the second or third decade of life. Several case reports have documented the development of chronic hypercapnia in patients with limb-girdle dystrophy who have severe diaphragm weakness or bilateral diaphragm paralysis as the basis for hypercapnia. However, not all patients with limb-girdle dystrophy develop hypercapnia. Most patients have moderate respiratory muscle weakness with normal gas exchange.

Acid Maltase Deficiency (Pompe Disease)

Two metabolic myopathies, acid maltase deficiency and mitochondrial myopathy, have received attention as potential causes of respiratory failure. Acid maltase deficiency is a type I glycogen storage disease due to the deficiency of the lysosomal enzyme responsible for hydrolysis of both the α 1–4 and α 1–6 linkages of glycogen. The disease presents in three clinical forms: infantile, childhood, and adult. In adult-onset disease, onset usually occurs after 20 years of age and presents with progressive proximal muscle weakness. The diagnosis may be difficult to establish in some patients, as respiratory failure or sleep-related complaints, secondary to respiratory deterioration during REM sleep, may be the initial presentation. Diagnostic studies include elevated serum muscle enzymes; myopathic changes on electromyography, and vacuoles filled with lysosomal breakdown products on muscle biopsy. Enzyme replacement therapy with recombinant human acid maltase, alglucosidase alfa, is now available for both early- and late-onset disease. In a study of 99 patients with late-onset Pompe disease, treated for 78 weeks with biweekly infusions of alglucosidase, the investigators found an improvement in FVC and 6-min walk distance.[148]

Mitochondrial Myopathy

Mitochondrial myopathy represents a heterogeneous group of disorders that affect mitochondrial function and may present as complex multisystem disorders with brain and striated skeletal muscle being the predominant organs affected: (1) Kearns-Sayre syndrome; (2) myoclonic epilepsy, "ragged red fibers," and mitochondrial myopathy; and (3) encephalopathy, lactic acidosis, and stroke-like episodes. The clinical manifestations may be broad and include myalgia and exercise intolerance, proximal muscle weakness, and external ophthalmoplegia with unexplained respiratory failure. All three disorders are characterized by hypoventilation and depressed responses to hypoxia and hypercapnia and, in some cases, unexplained respiratory failure. Skeletal muscle biopsy establishes the diagnosis of mitochondrial myopathy by showing "ragged red fibers," which are accumulations of mitochondria identified with modified trichrome staining. Treatment is supportive. Once identified, patients should be cautioned regarding the use of sedatives, and special attention is required when sedation or surgery is planned.

TREATMENT

Principles in management of respiratory dysfunction in patients with neuromuscular disease include (1) preventative therapies designed to minimize the impact of impaired secretion clearance, alveolar hypoventilation on gas exchange, and lower respiratory tract infections, and (2) stabilization of patients who develop acute or chronic respiratory failure. Because patients with neuromuscular disease usually have nonpulmonary symptoms and signs before the onset of respiratory problems, preventive actions can be taken to preserve their respiratory status.

In neuromuscular disorders causing bulbar dysfunction, swallowing precautions and airway control measures are required. With advanced bulbar symptoms, upper-airway control with a cuffed tracheostomy tube may be needed to protect the airway and facilitate suction of lower respiratory tract secretions, averting atelectasis and pneumonia. In patients with impaired cough, assisted coughing (e.g., ancillary hand thrust in the substernal location to increase intrathoracic pressure and expel secretions mouthward) may be helpful, along with posture drainage and the use of incentive spirometry. Treatment modalities used for treating pulmonary complications of neuromuscular disease include respiratory muscle training, mechanical ventilation (invasive and noninvasive), and glossopharyngeal breathing.

■ Diaphragmatic Pacing

To increase independence from mechanical ventilation, diaphragmatic pacing may be a treatment option in selected patients. Although phrenic nerve pacing by external stimulation has been well documented since the late 1940s, long-term phrenic nerve stimulation did not become a reality until a small implantable electrode and receiver were developed in the late 1960s.

Diaphragmatic pacing consists of a radiofrequency transmitter and an antenna that discharges stimulatory signals to a receiver that when activated by radiofrequency waves, transmits electrical impulses in an electrode placed over the phrenic nerve. Surgery is required to implant the electrodes and receiver. Electrode implantation around the phrenic nerves can be achieved by a cervical or thoracic approach; however, the thoracic approach is preferred to ensure stimulation of

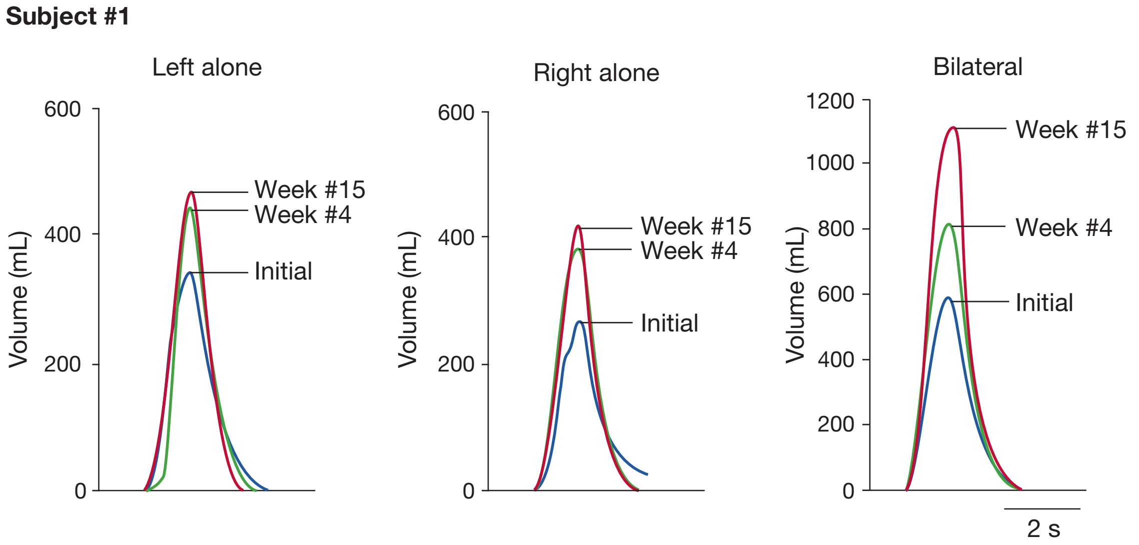

Figure 84-14 Reconditioning of the diaphragm as evidenced by increased inspired volumes initially, at 4, and 15 weeks postoperatively after left and right hemidiaphragm and bilateral diaphragm contraction via diaphragmatic electrode pacing. *(Data from DiMarco AF, Onders RP, Ignagni A, et al. Phrenic nerve pacing via intramuscular diaphragm electrodes in tetraplegic subjects. Chest. 2005;127(2):671–678.)*

all phrenic nerve roots while avoiding the brachial plexus. The subcutaneous receiver is usually placed in the lower anterolateral rib cage to allow it to be superficial, but in an area where soft-tissue movement is limited.[149–151] The subject must have intact phrenic nerves in order for the procedure to be successful, and the phrenic nerve is typically assessed by measuring conduction times along the nerve. Electric stimulation is applied transcutaneously in the neck region and surface diaphragm EMG is monitored. The nerve conduction time can then be calculated; normal is approximately 7.5 to 9 ms.

Diaphragmatic pacing has a number of potential limitations, including its high cost, the potential to fail abruptly, the development of upper-airway obstruction, and the induction of diaphragm fatigue. On the other hand, successful implantation allows patients to be independent from ventilatory support for prolonged periods, and to speak more freely.

While implantation of phrenic nerve electrodes has become an accepted procedure, there is ongoing research into placing diaphragmatic electrodes laparoscopically, and the technique has been performed successfully in a few centers.[152] This approach would be less invasive and more cost efficient, and would have less morbidity than the current approach. Two electrodes are placed on each hemidiaphragm near the motor points of the phrenic nerve. Initially, removable suction electrodes are placed until a location is found that induces maximal contraction of the diaphragm and a large intra-abdominal pressure change by both twitch and high-frequency stimulation. The wires are then brought through the skin and connected to the stimulator. Because patients on chronic mechanical ventilation develop diaphragm atrophy,[153] a reconditioning period is required before the restoration of maximal diaphragm function.

Figure 84-14 shows the tidal volume generated gradually increased with time as the muscle is reconditioned and the tidal volume is greatest with bilateral stimulation. In a case series using this technique, 3 of 5 subjects achieved independence from mechanical ventilation. One other was free of mechanical ventilation for 20 h per day, and the other did not have activation of the diaphragm. This individual most likely did not have intact phrenic nerves.[150]

Intact phrenic nerves are required for successful intramuscular diaphragm pacing as evidenced by animal studies showing no diaphragm activation with intra-muscular pacing after transection of the phrenic nerves. This probably occurs because the mechanism of intramuscular pacing is by stimulation of phrenic nerve roots in the diaphragm.

Because the intercostal muscles are capable of contributing up to 35% to 40% of the vital capacity they should be able to liberate a subject from mechanical ventilation if stimulated through pacing. In animal models, stimulation of the ventral surface of T1–T3 resulted in maximal inspired volumes, and when combined with bilateral phrenic nerve pacing resulted in tidal volumes that approached the inspiratory capacity. However, when applied to a group of spinal cord injury patients with phrenic nerve damage; very little volumes were generated with stimulation of the ventral aspect of T1–T3, and subjects were unable to breathe without mechanical ventilation for short time periods (20 min to 2.45 h). This discrepancy between animal and human studies may be secondary to the different shape of the human thoracic cage or the reduction in rib cage and lung compliance in those with tetraplegia. Additionally, stimulation of T1–T3 resulted in the movement of several nonrespiratory muscles, which led to hypertrophy of the upper trunk musculature.[150] A follow-up trial that combined intercostal pacing with unilateral diaphragm pacing in a small group of patients had unilateral phrenic nerve injuries in addition to spinal cord injury. All these patients were able to have significant periods of time free from mechanical ventilation.[154] The main limitations to this approach remain contraction of nonrespiratory muscles, which makes the process metabolically inefficient and can lead to uncontrollable muscle activity.

Those who appear to benefit from diaphragmatic pacing are ventilator-dependent patients following high cervical cord injury. Approximately one-third of patients with high cervical spinal cord injuries may be suitable for this type of treatment. Although short-term improvements are noted in terms of ventilator independence and improvement in functional status, no long-term studies demonstrating efficacy have been published to date.

CHAPTER 85

Asbestos-Related Lung Disease

William N. Rom
Jun-Chieh J. Tsay

INTRODUCTION

Asbestos is a fibrous hydrated magnesium silicate with commercial use due to its indestructible nature, fire resistance, and easy transformability into industrial products from yarn to insulation block to brakes. Asbestos fibers are generally defined as long, thin fibers with a length-to-width ratio (aspect ratio) of 3:1. There are six commercial forms of asbestos: chrysotile, crocidolite, amosite, anthophyllite, actinolite, and tremolite. Most of the asbestos used in the United States has been chrysotile, a serpentine form of asbestos. Other asbestos types are the amphiboles—notably amosite, mined in South Africa, and crocidolite, mined in the Cape Province of South Africa and in Western Australia. These asbestos fiber types have strikingly different physical characteristics: chrysotile tends to be wavy and long and occurs in bundles; crocidolite is needle-shaped with many long fibers; and amosite is similar to crocidolite but generally thicker. Asbestos fibers accumulate in the interstitium of the lung and are coated by iron and hemosiderin in a beaded, clubbed fashion referred to as ferruginous or asbestos bodies.

Initially, asbestos was widely used in fireproof textiles and later as insulation for boilers and pipes. Thereafter, asbestos was used in yarn, felt, paper, millboard, shingles, paints, cloth, tape, filters, wire insulation, cement pipes for potable water, gaskets, friction materials including brake linings, and roofing and floor products. Asbestos was extensively used for ship construction during World War II. Occupational exposure to asbestos in the United States now primarily occurs during maintenance activities or remediation of buildings containing asbestos. The Occupational Safety and Health Administration (OSHA) has estimated that 1.3 million workers in general industry continue to be exposed to asbestos, and the National Institute for Occupational Safety and Health (NIOSH) estimates that 44,000 mine workers might be exposed to asbestos fibers or amphibole cleavage fragments, especially tremolite. Although the European Union and 55 countries have banned imports and use of asbestos, approximately 2 million tons are used worldwide. Asbestos is mined in Eastern Europe and Asia where asbestos products are manufactured for use in insulation, roofing, and construction. Globalization has resulted in export of asbestos to developing countries for manufacture and export to other developing countries with concomitant increase in asbestosis and mesothelioma.[1] In 2004 the WHO estimated 107,000 global deaths from asbestos-related diseases. However, current estimate suggest that asbestos causes 255,000 deaths annually (3500 asbestosis, 30,000 mesothelioma, and 184,000 lung cancer), and an estimated $410 billion loss due to occupational cancer and $340 billion due to asbestos exposure at work.[2]

TYPES OF EXPOSURE

Primary asbestos exposures occurred in miners and millers. Secondary exposures occurred in manufacturing plants using asbestos in the production of textiles, friction materials, vinyl tiles, and insulation materials. Epidemiologic studies focused on cohorts in these plants, since asbestos fiber type was often specified, and dust measurements were obtained. These studies demonstrated that intensity and duration of exposure play an important role in the prevalence of asbestos-related disease. Common trades with asbestos exposure include sheet metal work, plumbing, pipefitting, insulation, railroad and utility power plant work, and school or building custodians. Prevalence of radiographic opacities in asbestos insulation workers exposed prior to the 1970s reached 50% in long-term workers and was approximately 15% in sheet metal workers. There is a long latency period between exposure and manifestation of asbestos-related disease, making identification and intervention difficult.

Although measurements of airborne asbestos fibers were seldom made, the most significant exposures appear to have occurred in the construction trades. These trades included asbestos insulators (called "laggers" in the United Kingdom), who mixed asbestos cement on site to insulate joints and elbows on pipes; boilermakers and sheet metal workers, who worked adjacent to the asbestos workers; and electricians, carpenters, plumbers, and others who worked in the vicinity of work requiring asbestos exposure. These exposures were mainly to chrysotile asbestos, since practically no crocidolite was imported into the United States, and only small amounts of amosite were admixed. Asbestos workers and other construction workers wore their asbestos-covered clothes home, exposing their wives and children when greeting them or while washing their garments. These household contact exposures are often referred to as *indirect exposures,* and those exposed while working near asbestos workers are called *bystander exposures.*

Current estimates suggest 35,000 U.S. lung cancer deaths per year are related to asbestos exposure, while the National Occupational Respiratory Mortality System, which has been tracking asbestosis and mesothelioma deaths since 1968, showed that death rates have peaked at 1400 death/year and 3100 death/year, respectively. Asbestosis is the cause of about 11% of deaths in asbestos workers; interestingly, the most important determinant is radiographic profusion score, with rates increasing from 2.4% to 10.98% and 35.4% with profusion category increasing from 1 to 3.[3] Profusion of irregular opacities is categorized into four levels ranging from 0 to 3, with 12 subcategories (0/0 to 0/1 to 1/0 up to 3/4) for the most dense fibrosis according to a scale agreed to by the International Labor Organization. Dyspnea, a low FVC, and/or physical examination findings typical of interstitial fibrosis (rales, clubbing, or cyanosis) raise the risk of death from asbestosis two- to sixfold.[3]

NONMALIGNANT PLEURAL MANIFESTATIONS

Pleural disease is the most common manifestation of asbestos exposure. The nonmalignant manifestations of asbestos exposure in the pleural space include circumscribed pleural plaques, diffuse pleural thickening, rounded atelectasis, and asbestos-related pleural effusions.[4]

Pleural Plaques

Important pathogenetic and clinical features of pleural plaques are discussed below.

Pathology

Pleural plaques are the most common manifestation of asbestos exposure. They are focal, irregular, raised white lesions found on the parietal and, rarely, the visceral pleura. The plaques may be small or extensive; commonly they occur in the lateral and posterior midlung zones, where they may follow rib contours and the diaphragm. They commonly enter lobar fissures and can invade the mediastinum or pericardium; rarely do they invade the apices or costophrenic sulci. Histologically, asbestos-related pleural plaques are characterized by a paucity of cells, extensive collagen fibrils arranged in a basket-weave pattern, and a thin covering of mesothelial cells. The parietal pleura is uniformly involved, with minimal thickening of the visceral pleura. The two pleural surfaces are free of adhesions. Pleural calcifications frequently develop in these fibrohyaline lesions as the length of time from exposure increases. Exposure to asbestos is the most frequent cause of pleural plaques.

Pathogenesis

Two theories have been proposed for the pathogenesis of pleural plaques. The most plausible is based on the direct effects of fibers that reach the pleural space. Asbestos fibers—the short, thin ones in particular—have been shown to be transported by subpleural lymphatics to the pleural space. In the pleural space, it is believed that they scratch, injure, and irritate the pleural surface, leading to hemorrhage, inflammation, and eventually fibrosis. The plaques are submesothelial. Mesothelial cells appear to play an important role in the pathogenesis of these lesions: they internalize asbestos fibers via an integrin receptor that recognizes vitronectin; in vitro pleural mesothelial cells also can synthesize collagens (types I, III, and IV), elastin, laminin, and fibronectin. In keeping with the submesothelial location of the plaques, cultured mesothelial cells can organize these macromolecular connective tissue components into an assemblage of extracellular matrix that is limited to the base of the cell.

Epidemiology and Natural History

Hyaline and calcified pleural plaques have been noted to be an index of exposure to asbestos. In shipyard workers, the frequency of pleural abnormalities was approximately 10 times that of parenchymal disease. The greater the exposure, the more likely the worker was to have extensive calcified pleural plaques as well as parenchymal fibrosis. The intensity of the exposure has been noted to be an important determinant of the prevalence of these abnormalities. For example, among British shipyard workers, 36% of those with continuous exposure as "laggers" developed pleural plaques, while extensive pleural thickening and pulmonary fibrosis were seen in 5% and 7%, respectively. In contrast, those with intermittent exposure had a 6% prevalence of plaques and no pulmonary fibrosis. On average, the latency time for the appearance of plaques is 30 years, but the time can vary greatly. This variation can also be appreciated from studies of British shipyard workers in whom the prevalence of pleural plaques increased from 17% at 10 years after the first exposure to 70% at 30 years among those with continuous exposure; for those with intermittent exposures, the prevalence increased from 1% at 10 years to 16% at 30 years.

All asbestos fibers are equally capable of inducing pleural plaques: Pleural plaques are found in U.S. insulators or shipyard workers exposed to chrysotile or amosite, as well as miners in Western Australia who were exposed to crocidolite.

In addition to occupational exposures, environmental, domestic and residential exposures have been implicated in the production of pleural plaques. Evidence for the latter is the remarkably high rates of pleural calcification (up to 45%) in some rural areas of Greece, Corsica, Cyprus, and Turkey where outcroppings of tremolite asbestos have been used to whitewash houses. Pleural plaques have been noted from environmental exposure to tremolite asbestos fibers contaminating vermiculite mining and milling in Libby, Montana.

Clinical and Physiologic Features

In the absence of concomitant asbestosis or obliteration of the costophrenic angle, pleural plaques are usually asymptomatic. Most often they are incidental findings on chest radiographs. In addition, they do not cause significant abnormalities such as pleural rubs, rales, or rhonchi on auscultation of the chest.

Pleural disease has been recognized as a cause of reduced pulmonary function since the 1970s. Among 998 shipyard workers in Groton, Connecticut, who had 15 or more years of asbestos exposure, 17% of those with pleural changes had a forced vital capacity (FVC) under 80% of predicted; for those with normal chest radiographs, 9% had decreased vital capacities. In those with normal chest radiographs, the values were significantly reduced only among smokers and ex-smokers. Recent studies that have applied stepwise regression analysis to data from insulation workers have disclosed a significant inverse relationship between FVC and an integrative pleural index for patients with circumscribed pleural plaques.[5] Even among those with pleuroparenchymal abnormalities, the pleural index was found to make a significant contribution to decrements in FVC, independent of that due to parenchymal abnormalities.

In nonsmoking asbestos workers with circumscribed or diaphragmatic pleural plaques, flow rates (FEV_1, $FEF_{25\%-75\%}$) have been reported to be reduced. In an epidemiologic study of 1211 sheet metal workers, pleural fibrosis was detected in 334 and was related to age, duration of exposure, pack-years of smoking, and the presence and degree of interstitial fibrosis.[6] After controlling for these confounders, multivariate regression analysis found that both plaques and diffuse thickening were independently associated with decrements in FVC, but not with decrements in the FEV_1/FVC ratio. Furthermore, diffuse pleural thickening was associated with a decrement in FVC twice as great as that seen with circumscribed pleural plaques. After confounding variables such as age, height, smoking status, and the presence of parenchymal abnormality as assessed by chest radiography and gallium scintigraphy were taken into account, there was a significant decrease in FEV_1 and FVC (222 and 402 mL, respectively) among workers who had pleural plaques or diffuse pleural fibrosis.[6] Meta-analyses of 20 studies estimated a summary effect of the decrements in percent predicted forced vital capacity (FVC 4.09% predicted; 95% confidence interval [CI], 2.31–5.86) and forced expiratory volume in 1 s (FEV_1 1.99% predicted; 95% CI, 0.22–3.77) associated with the presence of pleural plaques.[7]

Radiographic Features

The visualization of plaques on digital chest radiography depends on their thickness, their location, and the orientation of the radiographic beam.[8] As a result, they can be viewed in profile along the lateral chest wall or on en face with a rolled or holly-leaf pattern, especially if calcified (Fig. 85-1). Only a modest proportion of plaques detected at autopsy can be seen on digital chest radiography. Computed tomographic (CT) scanning increases plaque detection (increase in sensitivity and specificity).

The CT scan can recognize plaques at a much earlier and less well-defined state than digital chest radiography. The CT scan is particularly useful for perivertebral and pericardiac plaques, and high-resolution CT scanning (HRCT) helps to establish the presence of diaphragmatic lesions. In all cases, the CT scan can help to differentiate plaques from extrapleural fat pads and can detect concomitant parenchymal abnormalities that may be difficult or impossible to see on the PA chest radiograph.

Diagnosis

Pleural plaques due to asbestos exposure are usually bilateral (80% of the time), whereas unilateral pleural plaques may be due to trauma, previous tuberculosis, or, rarely, other causes, such as

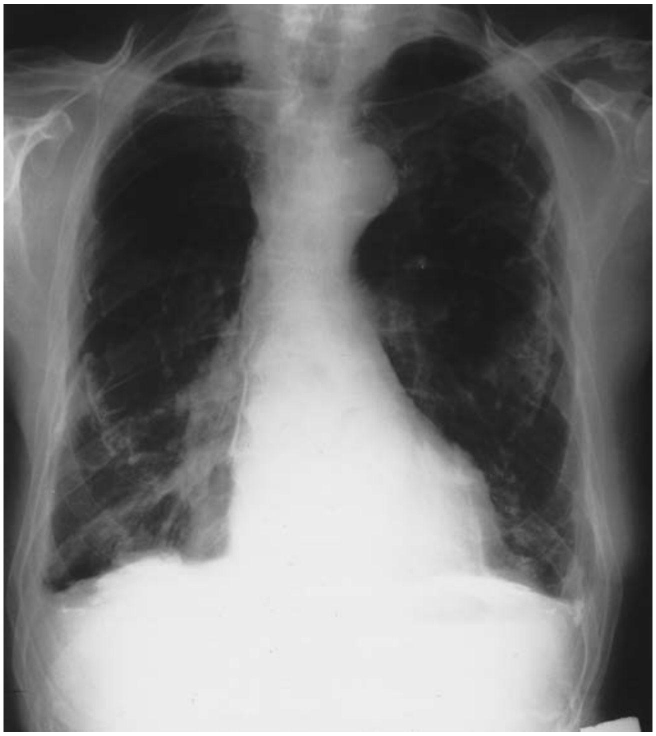

Figure 85-1 Posteroanterior (PA) chest radiograph of a 75-year-old man who worked in a shipyard during World War II insulating ships. The radiograph shows bilateral calcified pleural plaques en face and on top of the diaphragm. The pleura is diffusely thickened bilaterally and the costophrenic angles are blunted. Mediastinal pleural calcification is present on the right. *(Reproduced with permission from Dr. Timothy Harkin.)*

collagen vascular disease. The lesions are usually stable and remain the same size for months. This helps to differentiate plaques from pleural tumors. Histologic tissue examination is not necessary for diagnosis the vast majority of the time.

Treatment

No specific treatment is required for asbestos pleural plaques. Since they are markers of asbestos exposure and identify patients at risk for other asbestos-related disorders, medical surveillance, including periodic CT scans and blood biomarkers, is recommended.[9]

■ Diffuse Pleural Thickening

Pleural thickening, another common manifestation of asbestos exposure, is discussed below.

Pathology

Pleural fibrosis in persons who have been exposed to asbestos has been well described. The fibrotic responses can be localized or diffuse and either unilateral or bilateral. Macroscopically, the lesions vary in thickness from a whitish discoloration of the lung surface to a thick white peel that can encase significant pulmonary structures. Diffuse pleural thickening is most often seen as a continuous sheet that is 5 to 10 cm in craniocaudal extent, and in 90% of patients it affects the costophrenic angle. Interlobar and interlobular fissures are commonly involved. Whereas pleural plaques predominantly affect the parietal pleura, diffuse pleural fibrosis occurs most commonly as part of a fibrotic process of the visceral pleura and subadjacent interstitium.

Pathogenesis

Diffuse pleural thickening has been proposed to result from three different mechanisms. The first is the confluence of large pleural plaques, and the second is the extension of subpleural fibrosis to the visceral pleura. The most common pathogenic mechanism is thought to be the fibrotic resolution of a benign pleural effusion, producing diffuse pleural thickening. The importance of this mechanism is highlighted by the finding that about one-third of patients with diffuse pleural thickening have had a prior benign asbestos-related pleural effusion diagnosed by thoracentesis or on serial chest radiographs. The pathogenic mechanisms differentiating diffuse pleural thickening from circumscribed pleural plaques are not well defined. However, the fundamental mechanism of asbestos fibers activating macrophages and mesothelial cells to release growth factors and stimulate collagen formation is likely to be important in both. In the case of diffuse pleural responses, these fibers are deposited mainly in the parenchymal subpleural areas of the lung.

Clinical and Physiological Manifestations

Diffuse pleural fibrosis most often occurs long after short-term heavy exposure to asbestos. When mild, diffuse pleural fibrosis can be asymptomatic and discovered as an incidental finding on a chest radiograph obtained for another reason. The diffuse nature of the lesion, however, may lead to pulmonary symptoms, including dyspnea on exertion, chronic dry cough, and chest pain. As noted earlier, diffuse pleural thickening can cause a restrictive physiologic abnormality. The degree of physiologic abnormality varies with the degree of fibrotic response. On rare occasions, in patients with severe bilateral disease, respiratory insufficiency has occurred. Diffuse pleural fibrosis can increase in severity over time.

Radiographic Features

On the routine chest radiograph, diffuse pleural fibrosis presents as a continuous pleural opacity usually blunting the costophrenic angle. It can be unilateral or bilateral and seen in the presence or absence of concomitant asbestosis and pleural calcifications. Rarely, the pleural fibrosis will produce a fibrotic pseudotumor with a pleural basis (rounded atelectasis) (see below). CT scanning is particularly useful in delineating the relationship between diffuse fibrosis and other pleural abnormalities and differentiating pleural fibrosis from fat deposits.

Diagnosis

The diagnosis of diffuse pleural fibrosis is usually based on the clinical presentation and chest radiograph. The lesions of diffuse pleural fibrosis are not unique to asbestos-exposed persons and can represent old inflammatory reactions from tuberculosis, thoracic surgery, or hemorrhagic chest trauma. Differentiation among these causes is frequently based on a careful clinical history. Radiographic patterns are also helpful since bilateral interstitial changes in the lower lung zones in association with pleural plaques or calcifications strongly support a diagnosis of asbestos exposure. A biopsy may be required when the thoracic lesion is progressing or when malignancy is in the differential.

Treatment

As seen with circumscribed pleural plaques, there are no specific therapies for asbestos-related diffuse pleural fibrosis. Medical surveillance is required to detect disease progression, lung cancer, and mesothelioma.

■ Rounded Atelectasis

Rounded atelectasis is a rare complication of asbestos-induced pleural disease. It is caused by scarring of the visceral and parietal pleura and the adjacent lung, with the pleural reaction folding over on itself. The pleural surfaces then fuse to one another, trapping the underlying lung and leading to atelectasis. As a result of this alteration, a mass lesion that mimics lung cancer can be seen on the PA chest radiograph (Fig. 85-2). This lesion is most easily appreciated to be a pseudotumor with use of CT scanning. HRCT can noninvasively demonstrate continuity to areas of diffuse pleural thickening, evidence of volume loss in the adjacent lung, or a characteristic comet tail of vessels and bronchi sweeping into a wedge-shaped mass (Fig. 85-2).

CT scanning can also demonstrate stability over time (from months to years), which supports the diagnosis of a benign lesion, and pleural plaques or parenchymal changes, which support a diagnosis of asbestos exposure. In one clinical series of 74 patients with rounded atelectasis, 64 had significant asbestos exposure, and the lingula or right middle lobe was affected in 49 of the patients.[10]

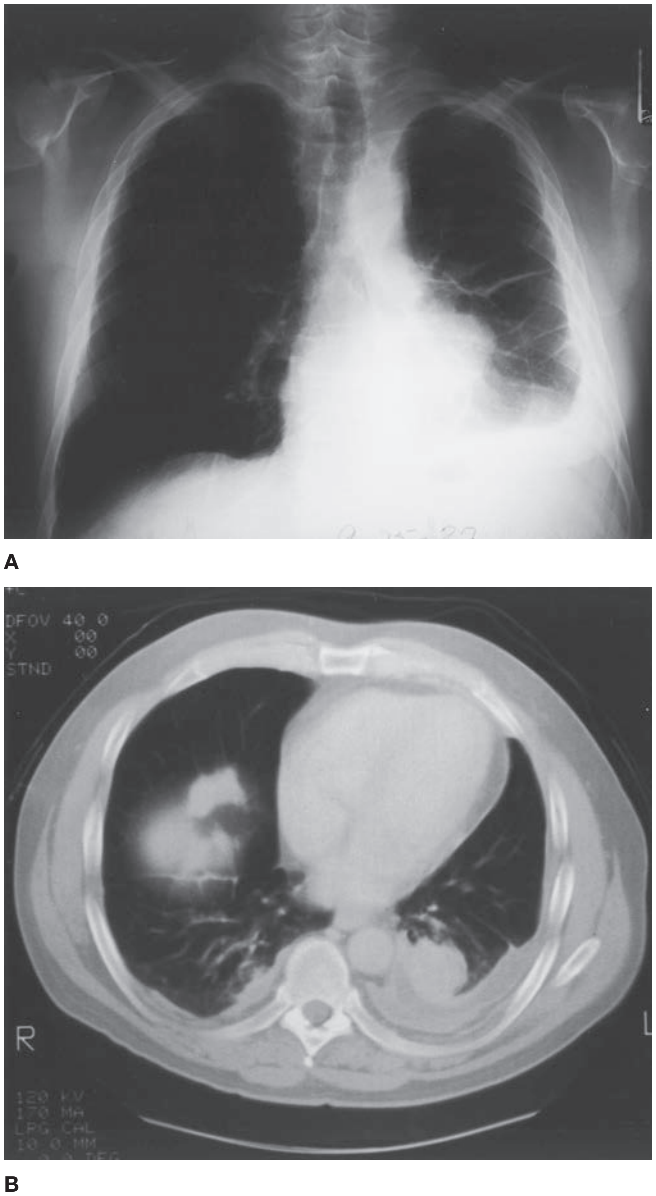

Figure 85-2 Rounded atelectasis and other pleural abnormalities in an asbestos worker. The chest radiograph (**A**) shows a left-sided pleural effusion, bilateral pleural thickening, greater on the left than on the right, and a mass in the left midlung field. HRCT (**B**) demonstrates the mass to be rounded atelectasis, with bronchovascular structures entering the trapped lung. It also reveals the pleural effusion, bilateral pleural thickening, and pleural plaques, one of which is on the right hemidiaphragm. *(Reproduced with permission from William M. Rom, MD, MPH.)*

HRCT scans localized most cases of rounded atelectasis to the lower, posterior portion of the lung; moreover, in one-third of the patients, the lesions were multiple. In most patients, rounded atelectasis occurs suddenly on a background of only plaques or a normal chest radiograph. In others, a slowly increasing pleural effusion may precede its appearance.

■ Acute Benign Pleural Effusions

Acute benign pleural effusions are common pleural manifestations in asbestos-exposed persons between 20 and 40 years of age. The latency period for these effusions is shorter than for pleural plaques, malignant mesotheliomas, or pulmonary malignancies. Benign pleural effusions generally occur earlier after exposure than do other asbestos-related processes. The latency is shorter—for example, 12 to 15 years rather than >20 years after the first asbestos exposure compared to pleural plaques or asbestosis.

About 50% of the patients with acute benign pleural effusions are asymptomatic. When patients are symptomatic, the manifestations may be those of a pleurisy (chest pain, chest tightness, dyspnea, cough, and fever). Physical examination reveals the signs of a pleural effusion; a pleural friction rub may be heard. The effusions are exudative and often bloody; glucose concentrations are normal. Mesothelial cells in effusions are found in about 50% of patients. In about 25% of patients, the fluid is eosinophilic. Rarely are asbestos bodies found even though they may be present in underlying lung tissue.

The designation “benign” refers to the lack of evidence of malignancy. The collections may persist for 6 months or more. They frequently clear spontaneously, only to recur on the contralateral side. However, a benign asbestos pleural effusion is a risk factor for the development of pleural thickening, especially diffuse pleural fibrosis. The diagnosis of acute benign pleural effusions is one of exclusion. Thoracentesis is essential. Pleural biopsy is frequently required to rule out other causes of pleural effusions, including mesothelioma. The usual pathologic findings are a chronic fibrous pleurisy with minimal cellularity. Diffuse malignant pleural mesothelioma invariably presents as a pleural effusion, but pleural mass lesions are usually seen on CT scan, which are absent in benign asbestos effusions.

ASBESTOSIS

Important pathologic and clinical aspects of asbestosis are discussed below.

■ Pathology

Asbestosis is the interstitial pneumonitis and fibrosis caused by exposure to asbestos fibers.[4] Early lesions are characterized by discrete areas of fibrosis in the walls of respiratory bronchioles. The septa adjacent to the respiratory bronchioles are often thickened, and the fibrosis sometimes appears to spread outward from the bronchioles. In addition to the peribronchiolar fibrosis, there is an intense peribronchiolar cellular reaction that may narrow and obstruct the airway lumen. Macrophage accumulation is a prominent feature of this cellularity. Proliferation of type II alveolar epithelial cells is enhanced. The interstitium may contain collections of lymphocytes; smooth muscle proliferation may be prominent in areas of remodeling; and buds of loose connective tissue may be seen within the alveoli (Fig. 85-3).[11] Initially, the disease usually involves first-order bronchioles; subsequently, second- and third-order bronchioles are affected. As the disease progresses, the fibrosis becomes diffuse, the architecture of the lung undergoes extensive remodeling, and honeycombing supervenes. In contrast to other pneumoconioses, lymph node enlargement and progressive massive fibrosis do not occur. Pathologically, the alterations seen

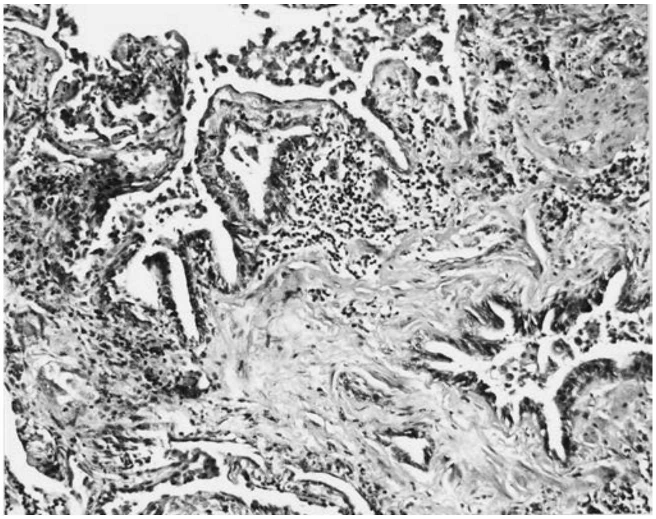

Figure 85-3 Lung tissue from a 64-year-old asbestos insulator with 46 years of exposure to asbestos while insulating pipes. His chest radiograph revealed extensive irregular opacities and bilateral pleural thickening. The figure illustrates peribronchiolar fibrosis, interstitial chronic inflammation, accumulation of macrophages in the airspaces, and proliferation of type II pneumocytes. *(Reproduced with permission from Rom WN, Travis WD, Brody AR. Cellular and molecular basis of the asbestos-related diseases. Am Rev Respir Dis. 1991;143(2):408–422.)*

in asbestosis cannot be differentiated from many other interstitial fibrotic disorders except for the presence of asbestos bodies and uncoated asbestos fibers.

■ Pathogenesis

Asbestos fibers are deposited at airway bifurcations and in respiratory bronchioles and alveoli by impaction, sedimentation, and interception. Fibers then migrate into the interstitium, in part via an uptake process involving type I alveolar epithelial cells. This causes alveolar macrophages to accumulate in the alveolar ducts, peribronchiolar interstitium, and alveolar spaces, constituting an alveolar macrophage alveolitis.[12] Following this initial macrophage alveolitis, most fibers are cleared, leaving the lungs unscarred. If clearance is incomplete, fibrosis can ensue. The degree of fibrosis in asbestosis relates, in general, to the lung dust burden. If the retained dust load is great, tissue reaction and macrophage alveolitis are proportionately more intense, greater injury occurs, and chronic and progressive lung disease can develop.

The macrophage alveolitis that is seen in early stages of asbestosis results from monocyte recruitment from the blood and in situ macrophage replication. These cells appear to play an important role in the pathogenesis of the inflammation and fibrosis seen in this disorder. Morphologically, they express an activated phenotype characterized by cellular multinucleation and a striking increase in membrane ruffling, surface blebbing, and lysosomes and phagolysosomes.[13] These macrophages are presumably attempting to engulf and clear the asbestos fibers. This process is not uniformly successful, however. First, the fibers induce apoptosis in the cells. Although the coating of asbestos fibers to form asbestos bodies makes them less toxic, the vast majority of fibers in the lung remain uncoated. Second, the long fibers cannot be completely phagocytosed. Finally, chrysotile asbestos fibers tend to split longitudinally. This generates additional fibers that can multiply the asbestos effect even after exposure has ceased. As a result, asbestos has a prolonged residence, surprising mobility, and penetrates the interstitium of the distal lung.

These characteristics probably contribute to the pathogenesis of the disease, since—in contrast to inert particles, which can be ingested by macrophages and cleared without generating a significant response—asbestos fibers stimulate macrophages to produce a variety of important cytokines and growth factors.[14] Both asbestos and silica are phagocytosed by alveolar macrophages, which then activates them to release cytokines, growth factors, and oxidants. These include platelet-derived growth factor (PDGF); insulin-like growth factor 1 (IGF-1); transforming growth factor β; the cytokines interleukin 1β (IL-1β), tumor necrosis factor α (TNF-α), and IL-8; the matrix molecule fibronectin; oxygen free radicals; and matrix metalloproteinases.[11–15] The oxygen radicals contribute to tissue injury via direct cell cytotoxicity and lipid peroxidation of membrane components. IL-8 recruits neutrophils to sites of disease activity. PDGF, IGF-1, IL-1β, TNF-α, and fibronectin contribute to tissue fibrosis by stimulating fibroblast proliferation and chemotaxis and collagen biosynthesis.[10] In vitro exposure of mononuclear phagocytes to silica, asbestos, or coal activates transcription factors including AP-1 and NF-κB, with subsequent release of cytokines and growth factors.

Bronchoalveolar lavage (BAL) in asbestosis has demonstrated an alveolar macrophage alveolitis with a modest increase in neutrophils.[12] This neutrophilia correlates with the finding of rales on physical examination and oxygenation parameters and is apt to be more pronounced in patients with advanced disease. In patients with asbestosis, ^{67}gallium lung scans may also be positive. Clinically apparent asbestosis occurs only after a significant latent period. However, studies using BAL, CT scanning, and ^{67}gallium scanning have demonstrated that inflammatory events occur well before the onset of clinical disease. Thus, it is likely that the initial exposure induces inflammation and injury that persist through the latent or subclinical phase and develops into the clinical disease diagnosed by classic radiography and other techniques. Current concepts of the pathogenesis of the disease link inflammation and fibrosis in a causal fashion.[11]

■ Epidemiology

The prevalence of parenchymal asbestosis among asbestos workers increases as the length of employment increases. This is illustrated in an early report in which investigators analyzed the chest radiographs of 1117 New York and New Jersey asbestos insulation workers. They found asbestosis in 10% of the workers who had been employed for 10 to 19 years, in 73% of those who had worked for 20 to 29 years, and in 92% of those who had worked 40 or more years.[16] A similar dose–response relationship was found in the asbestos cement industry. Among "bystanders" (i.e., among sheet metal workers who worked in close proximity to insulation workers) the overall prevalence of asbestos-related changes was 31%, including 9% who had only pleural abnormalities and 12% who had parenchymal abnormalities.[17] Among those who had been in the trade for 40 years or more, 41.5% had radiographic signs of asbestos-related disease.

Cigarette smoking can affect the expression of asbestosis.[18] Smokers without dust exposure may have a few irregular radiographic opacities, probably representing acute or chronic bronchitis or bronchiectatic changes in the lung parenchyma. Both smokers and ex-smokers have a higher frequency of asbestos-related irregular opacities on their chest radiographs than do their nonsmoking colleagues. Smoking does not alter the expression of asbestos-induced pleural fibrosis. However, cigarette smoking may interfere with the clearance of inhaled asbestos, thereby potentiating the effects of the dust in the lung.

■ Natural History

Following asbestos exposure, asbestosis becomes evident only after an appreciable latent period. The duration of exposure and its intensity influence the prevalence of radiographically evident parenchymal pulmonary fibrosis. Because work sites around the world increasingly meet recommended control levels, high-level exposure to asbestos is now uncommon and clinical asbestosis is becoming a less severe disease that manifests after a longer latent interval. In Western Australian crocidolite workers, a median of 14 years elapsed before asbestosis was detectable radiographically (range, 2–34 years). In retired Quebec chrysotile miners and millers, the frequency of pleuroparenchymal lesions was 31%, and progression of parenchymal opacities occurred in 9.3%; progression was confined to the more heavily exposed group.[19]

One approach to the study of low-level exposure is to evaluate the outcome from short-term exposure. In such a study in an amosite asbestos factory, employment for even as little as 1 month resulted in a 20% prevalence of parenchymal opacities: one-third of the participants had pleural abnormalities after 20 years of follow-up; it is significant that both "first attacks" and progression of established radiographic abnormalities occurred 20 and more years after exposure had ceased.[20]

Radiographic asbestosis, once established, may remain static or progress. Rarely has regression been recorded. The factors that determine the outcome are poorly understood. The level and duration of exposure (i.e., cumulative exposure) appear to be prognostic factors. Progression is also considerably more common in persons who already have radiographic abnormalities. This fact provides the basis for the advice that further exposure is to be avoided once the diagnosis of parenchymal asbestosis has been made.

Clinical and Physiologic Features

Dyspnea on exertion is the earliest, most consistently reported, and frequently the most distressing symptom of asbestosis. Often dyspnea is accompanied by a persistent cough, which can be spasmodic, with sputum production. Chest tightness is not uncommon, and wheezing also can occur. In a cross-sectional survey of 816 asbestos-exposed workers using a respiratory symptoms questionnaire, cough, phlegm, wheeze, and dyspnea were inversely related to pulmonary function.[21] Cough, phlegm, and chronic bronchitis were associated with a 2% to 8% reduction in FVC and FEV_1; the reduction in these measurements was more significant with wheeze and dyspnea, which caused an 11% to 17% reduction. Similarly, the prevalence of dyspnea on the level less than one block among asbestos insulators increased in stepwise fashion from 19% in patients with category 1 chest radiographic abnormalities to 35% in patients with category 2 chest radiographs and to 49% in patients with category 3 radiographic abnormalities.[22]

Rales are a distinctive feature of asbestosis. They are usually bilateral, late to pan-inspiratory in timing, heard best at the posterior lung bases, and not cleared by coughing. They differ in quality and timing from the crackles of bronchitis, which tend to be fewer and earlier. The crackles of asbestosis appear first at the bases in the midaxillary line and tend to spread toward the posterior bases. In prevalence surveys, approximately 83% of patients with higher radiographic categories of asbestosis had bilateral rales. In a study of 42 patients with a clinical diagnosis of asbestosis, in 40 the chest radiograph showed at least 1/0 profusion of irregular opacities, 36 had rales, 36 had dyspnea, and 22 had digital clubbing.[23]

The characteristic pulmonary function changes of asbestosis are a restrictive impairment with a reduction in lung volumes (especially FVC and total lung capacity), decreased lung diffusing capacity ($D\textsc{l}_{CO}$), and arterial hypoxemia.[24] Large-airway function, as reflected in the FEV_1/FVC ratio, is generally well preserved. Among the 1117 asbestos insulators in New York and New Jersey, the frequency of an abnormal FVC increased to more than 50% as follow-up was prolonged. In a larger cohort of 2611 asbestos insulators, the FVC percent predicted decreased as the profusion of irregular opacities on the chest radiograph increased; pleural thickening exaggerated the decrease for each category of profusion. For each category of profusion, diffuse pleural thickening caused a further decrease (at least 10%) in FVC percent predicted compared with circumscribed plaques.[25]

Mild airway obstruction can also be seen in nonsmokers with asbestosis.[26] These patients usually have a restrictive pattern of lung function, increased isoflow volume, and increased upstream resistance at low lung volumes. Open lung biopsies from a limited number of these patients suggest that these obstructive findings may be due to peribronchiolar fibrosis, since they revealed peribronchiolar infiltrates with macrophages and fibrosis that extended into the adjacent interstitium. Therefore, it is not surprising that lesser grades of asbestosis can show a mixed restrictive and obstructive abnormality.

Long-term medical surveillance is recommended for all asbestos-exposed persons, especially those with radiographic abnormalities. Periodic physiologic assessments play an important role in these evaluations. Prospective assessments of asbestosis should include spirometry as most useful, and diffusing capacity to assess alveolo–capillary function.

Radiographic Features

In asbestosis, digital radiography reveals bilateral diffuse reticulonodular opacities, predominantly in the lower lung zones. The International Classification of the Radiographs of the Pneumoconioses uses the term *small irregular opacities* to describe the irregular linear shadows that develop in the lung parenchyma and obscure the normal bronchovascular branching pattern seen in disease-free lungs. This schema categorized the irregular or rounded opacities found on conventional PA chest radiographs according to size and expressed them on a 12-point scale. Category 0 was defined as a normal radiograph and category 1 as mild asbestosis. Typically, a profusion of irregular opacities at the level of 1/0 is taken as the break point between normal and abnormal.[4] Moderate asbestosis and advanced asbestosis were defined as category 2 and 3 chest radiographs, respectively. As duration from onset and intensity of exposure increase, there is an increase in prevalence and severity of asbestosis as reflected in the chest radiograph.

CT scanning has improved the sensitivity for detecting asbestos-related lesions (Fig. 85-4). It eliminates a common problem with digital chest radiographs—that is, the superimposition of pleural abnormalities over parenchymal lesions. It also enhances the attenuation discrimination for parenchymal opacities. As a result of more than 300 HRCT evaluations of persons with asbestos exposure, five HRCT features of asbestosis have been identified: (1) curvilinear subpleural lines, (2) increased intralobular septa, (3) dependent opacities, (4) parenchymal bands and interlobular core structures, and (5) honeycombing. These changes have been corroborated by histologic examination.[27] In asbestos-exposed workers, abnormal HRCT has been shown to correlate with restrictive physiologic abnormalities and abnormal diffusing capacities. HRCT is also extremely sensitive in documenting the asbestos-related pleural abnormalities discussed earlier. The presence of pleural plaques (particularly if they are bilateral) provides useful evidence that the parenchymal process is asbestos-related. Hilar node enlargement is not a feature of asbestosis, and progressive massive fibrosis also is uncommon. In a CT scanning trial for the early detection of lung cancer, a comparison was made between smokers with asbestos exposure ($n = 359$) to those without asbestos exposure ($n = 1038$).[28] Asbestos-exposed smokers had decreased FVC (76% vs. 85%; $p < 0.01$) and FEV_1 (64% vs. 85%; $p < 0.01$), and those with >20 years' asbestos exposure had a further reduction. Those with isolated pleural plaques had a significant reduction in FVC% predicted compared to those with no pleural plaques or radiographic abnormalities.

■ Diagnosis

Asbestosis is defined as parenchymal fibrosis, with or without pleural thickening, usually associated with dyspnea, bibasilar rales, and pulmonary function changes. To diagnose this disorder, one must establish the presence of pulmonary fibrosis and determine whether exposure has occurred of a duration and intensity sufficient to put the person at risk. A profusion of irregular opacities at the level of 1/0 is used as the break point between normal and abnormal in the evaluation of lung fields on the chest radiographs of asbestos-exposed persons. When radiographic or lung function changes are marginal, CT scanning often reveals characteristic parenchymal abnormalities as well as pleural plaques and/or pleural fibrosis. These lesions, particularly when bilateral, are strongly suggestive of asbestosis. The diagnosis of asbestosis must always be based on the chronologic occupational history with potential exposures. The features of the history that need to be defined include the duration, onset, type, and intensity of exposure. In taking the occupational history, it is important to keep in mind that intensity of exposure can be heavy even if duration of exposure is short. For example, heavy exposures were experienced by shipyard workers engaged in insulation application or removal in contained areas for brief periods aboard ship and by asbestos insulators during their apprenticeship when they unloaded asbestos sacks into troughs and mixed asbestos cement. Short, intense exposures of this sort, which lasted from several months to 1 or 2 years, can be sufficient to cause asbestosis. Exposures over 10 to 20 years are, however, usually necessary. The timing of the exposure also is relevant. Industrial hygiene controls in the 1960s and 1970s, especially in the construction trades, were not widely applied or enforced. Cohort studies have identified latency to be an important factor, with the prevalence of asbestosis increasing with time since the onset of exposure.

The specificity of the diagnosis of asbestosis increases with the number of consistent findings on chest film, the number of clinical features present (e.g., symptoms, signs, and pulmonary function changes), and the significance and strength of the history of exposure. The more significant the asbestos exposure the greater accuracy is the diagnosis. The more trivial the asbestos exposure, the less likely it is to be causal. Misclassification and diagnostic difficulty occur in patients with a heavy cigarette smoking history and concurrent emphysema (which also reduces the diffusing capacity). Patients with idiopathic pulmonary fibrosis (IPF) may have a history of asbestos exposure. These patients tend to be younger, however, and their asbestos exposure is usually casual, brief, and recent and can often be discounted. If an open lung biopsy is available, one or more asbestos bodies per high-power field (Fig. 85-5) or an asbestos fiber count per milligram of dry lung can be helpful to distinguish from IPF. In the absence of an adequate exposure history or in the presence of a confusing clinical presentation, biopsy material may be helpful in identifying the nature of the disease. It allows the pulmonary interstitial process to be compared to the known features of asbestosis and other interstitial disorders. Uncoated asbestos fibers are much more common than asbestos bodies, exceeding the frequency of coated fibers by anything from 5- to 10,000-fold. Although other inhaled particles may also become coated, most coated fibers found in human lungs have an asbestos core. Thus, the presence of asbestos bodies or asbestos fibers is considered the hallmark of exposure, past or current. Asbestos bodies can also be

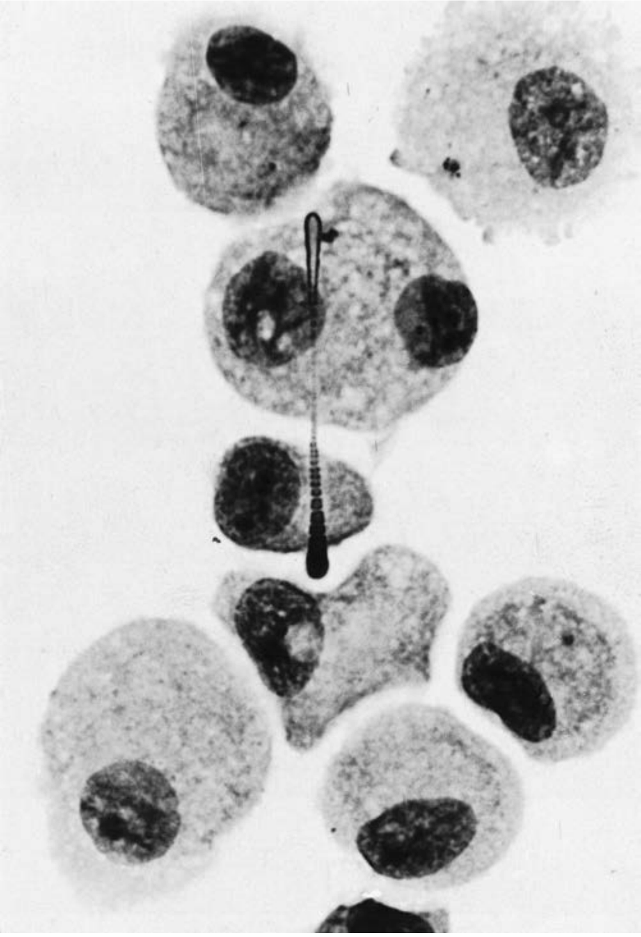

Figure 85-5 Light microscopic appearance of an asbestos body in a cytocentrifuged preparation of alveolar macrophages lavaged from a nonsmoking asbestos insulator (Wright–Giemsa stain, ×400). *(Reproduced with permission from William M. Rom, MD, MPH.)*

detected in BAL samples. Asbestos bodies in BAL correlate with heavy exposure, reduced lung function consistent with interstitial lung disease, and asbestosis.[29] This is illustrated in a large series of 563 patients: Those with asbestosis had a mean of 120 asbestos bodies per milliliter; those with pleural disease, 5 asbestos bodies per milliliter; and those with malignant mesothelioma or lung cancer, 8 asbestos bodies per milliliter of lavage fluid.[30] Of 49 patients with more than 100 asbestos bodies per milliliter of lavage fluid, 30 had asbestosis, 8 had pleural disease, 13 had mesothelioma or lung cancer, and 3 had an exposure history only. Others have estimated that one asbestos body per milliliter of BAL fluid correlates with 1000 to 3000 asbestos bodies per gram of dry lung tissue. Importantly, the Helsinki criteria guide the diagnosis of asbestosis and cancer with emphasis on a structured occupational history, clinical and radiographic findings, and recommendations for analysis of lung tissue for asbestos fibers and asbestos bodies.[31] These latter recommendations were as follows: greater than 0.1 million amphibole fibers >5 μm per gram dry lung tissue or greater than 1 million >1 μm using electron microscopy, greater than 1000 asbestos bodies per gram dry lung tissue, and greater than 1 asbestos body per milliliter of bronchoalveolar lavage fluid by light microscopy.

Treatment and Prognosis

Major causes of morbidity and mortality in patients with asbestosis include the progression of the underlying lung disease and the development of lung cancer and malignant mesothelioma. Longitudinal observations of asbestos-exposed trade workers have demonstrated accelerated declines in pulmonary function. In a study of 77 workers with a mean of 31 ± 1 years of occupational exposure, linear regression demonstrated a mean annual decline of 92 ± 28 mL/year in FVC, 66 ± 22 mL/year in FEV_1, and 14 ± 53 mL/year in total lung capacity.[32] At present, there is no established treatment for this disorder. Because of the risk of lung cancer and mesothelioma, medical surveillance with CT scans for those who also smoke more than 30 pack-years and age greater than 55 years on an annual basis is recommended.[33]

MALIGNANT MESOTHELIOMA

Malignant mesothelioma is an important complication of asbestos exposure, as discussed below. The reader is referred to Chapter 78 for additional detailed discussion of mesothelioma.

Pathology

Malignant pleural mesothelioma occurs in persons who have an exposure history to asbestos fibers, with 85% of men and 50% of women having an occupational history. In its early stage, the mesothelioma appears as multiple, small, grayish nodules on the visceral and parietal pleura that evolve to coalesce and form larger masses of tumors. These tumors then invade thoracic and other structures by direct extension. Fewer than 25% of malignant mesotheliomas are peritoneal in origin.

Mesotheliomas are conventionally classified into three histologic patterns: epithelial, sarcomatous, and mixed or biphasic; these patterns account for 50%, 20%, and 30%, respectively. The epithelial variant—in which neoplastic cells are arranged in papillary, tubular, or solid nest configurations—is most easily confused with metastatic adenocarcinoma. The sarcomatous variant has spindle-shaped cells that may be pleomorphic, with considerable mitotic activity.

The pathologic diagnosis of malignant mesothelioma may be difficult. In particular, the differentiation of malignant mesotheliomas, adenocarcinomas, and other tumors may be problematic. Histochemistry and immunohistochemistry may be helpful in making the distinction. Thus, in contrast to mesotheliomas, adenocarcinomas contain neutral mucin that stains positive with the periodic acid–Schiff stain and is often resistant to diastase. Hyaluronic acid, the major acid mucopolysaccharide in mesotheliomas, can be identified with the Alcian blue or colloidal iron stain. Removal by prior digestion with hyaluronidase increases the specificity of the reaction. In contrast, adenocarcinomas are negative for Alcian blue and colloidal iron. Mesothelial cells contain cytoskeletal filaments, including cytokeratin and vimentin; staining for these structures is not specific, since other tumor types are also positive. Carcinoembryonic antigen is absent in malignant mesothelioma but is present in up to 90% of adenocarcinomas. Similarly, the monoclonal antibody B72.3, generated against a membrane fraction of human metastatic breast cancer, was positive in 19 of 22 pulmonary adenocarcinomas but none of 20 mesotheliomas. Monoclonal antibody Leu MI is frequently positive in lung carcinomas and nonreactive with mesotheliomas.[34] Thyroid transcription factor 1 (TTF-1) is a marker for lung adenocarcinoma and is a positive prognostic factor.[35]

The ultrastructural features of malignant mesotheliomas also are noteworthy. Malignant mesotheliomas contain abundant tonofilaments, often organized into perinuclear bundles, and long, sinuous, slender surface microvilli. The microvilli sometimes show secondary and tertiary branching and may interdigitate with stromal collagen. Malignant mesothelial cells produce collagen, a prominent feature of the sarcomatous variant.

Malignant mesotheliomas are locally invasive, spreading along the pleural wall and invading the lung, mediastinal lymph nodes, and other thoracic and nearby structures. At autopsy, tumor may be found in the diaphragm, heart, liver, spleen, adrenals, gastrointestinal tract serosa, bone, pancreas, and kidneys. Between 50% and 80% of patients also have metastases.

About 10% of patients with a malignant mesothelioma are alive at 24 months. Survival is significantly longer for patients with an epithelial subtype or with a pleural rather than a peritoneal mesothelioma, and for those under 65 years of age.

The incidence of mesothelioma is increasing because of the cohort exposed to asbestos between 1940 and 1970. Incidence rates vary from a low of 11 to 13 per million per year in the United States to 33 per million per year in South Africa and to 66 per million per year in Western Australia.[36] These rates reflect mining and manufacturing industries and the location of crocidolite mines. Although the peak incidence in the United States may have passed since imports decreased after 1945, imports of asbestos in the United Kingdom reached their peak in the 1960s to 1970s. Thus, the peak of mesothelioma deaths in the United Kingdom is expected to occur in 2020, when up to 1% of men may die of the disease. Chrysotile was the major asbestos import to the United Kingdom, and half of this material went into the construction industry. Amosite was the leading amphibole import, and most of it went into insulation board. Thus, workers in the construction industry in the United Kingdom seem to be at greatest risk.

Epidemiology

In 1960, Wagner et al.[37] published a landmark paper demonstrating an association between malignant mesothelioma and asbestos exposure. They reported on 33 patients from South Africa, 28 of whom were exposed in the crocidolite mining region and 4 of whom were exposed in asbestos factories. They observed that mesotheliomas occurred 20 to 40 years after exposure to asbestos dust and found asbestos bodies in lung tissue from 8 of 10 patients from whom lung tissue was available for study. Subsequently, the importance of direct asbestos exposure was confirmed and the potential importance of indirect exposure to asbestos was recognized.

Evaluations of asbestos fiber content have shown a clear association between asbestos exposure and the occurrence of mesothelioma.[33] Epidemiologic studies have shown crocidolite to be a potent fiber type among South African and Western Australian asbestos miners and millers. Most mesotheliomas have occurred from chrysotile–amphibole mixtures, since chrysotile is the most common fiber in commercial use. The incidence of malignant mesotheliomas among chrysotile workers who came before the Workers' Compensation Board of Quebec was similar to that in western Australian crocidolite miners. Studies of Canadian cohorts have also indicated that high concentrations of chrysotile, or tremolite, are required to cause mesothelioma, and further suggest that chrysotile has weaker biopersistence than does tremolite, which is merely a contaminant in most ores. In the United States, amosite is the predominant amphibole found in lung tissue: in one study it was identified in 81% of 90 patients with mesothelioma; in this population, it accounted for 58% of all fibers at least 5 μm in length.[38] Finally, there is no association between smoking and malignant mesothelioma.

An epidemic of mesothelioma was reported in the Cappadocia region of Turkey where 40% of deaths were caused by the disease in several villages.[39] The exposure was to erionite, an aluminum silicate fibrous zeolite, and villagers used the stone to build their homes and whitewash their walls, and they carved rooms in the soft volcanic tuft. There also appeared to be a family concordance beyond the household exposure.[40] These villages have been abandoned to control the epidemic of mesothelioma.

Low levels of asbestos exposure can increase the risk of mesothelioma, for example, European case-control studies have shown that increasing exposure to ≥1 fiber/mL-year doubles or triples the risk.[41] Odds ratios of 4.8 for domestic exposure to asbestos (95% CI, 1.8–13.1) and 11.5 for neighborhood exposure to asbestos (95% CI, 3.5–38.2) have been reported.[41] There is a strong dose–response relationship with no lower threshold or safe level. The scientific basis for the mesothelial carcinogenicity of chrysotile has been established with epidemiologic studies, animal carcinogen assays, and pleural fiber burden studies.[41] Suzuki and Yuen used transmission electron microscopy to measure lung fiber burden in 168 cases of mesothelioma and found chrysotile to be the sole asbestos type in mesothelioma tumor tissue (73%) and in the lung (26%), and found that only 1% of the chrysotile fibers were ≥5 μm in length.[42] Cancer registries exploring mesothelioma have identified statistically significant occupations associated with asbestos exposure not previously recognized, including chemical engineers, machine operators, automobile mechanics, railroads, plumbers, welders, metal molders, coremakers, cabinetmakers, and postal workers.[43]

Pleural plaques have been recognized as a risk factor for mesothelioma and lung cancer probably because they represent a marker of significant asbestos exposure. In Sweden, a review of 1596 male radiographs with pleural plaques fulfilling strict radiologic criteria upon more than 20 years of follow-up found 50 lung cancers with 32.1 expected (O/E 1.6) and 9 mesotheliomas with 0.8 expected (O/E 11.25).[9] In France, CT scan screening for lung cancer among 5287 male subjects with past asbestos exposure and follow-up over 7 years identified 17 pleural mesotheliomas; a statistically significant association was observed with pleural plaques (hazard ratio [HR], 6.8 [95% CI, 2.2–21.4] after adjustment for time since first exposure and cumulative exposure index to asbestos).[44] In addition, there were 36 deaths from lung cancer that was also associated with pleural plaques (HR, 2.41 [95% CI 1.21–4.85] after adjustment for smoking and asbestos cumulative exposure index).[45] However, in two Australian cohorts including crocidolite miners and millers, the asbestos exposure was associated with lung cancer and mesothelioma (pleural thickening was associated with peritoneal mesothelioma) and not pleural disease.[46] Asbestosis was diagnosed in 32% of the Australian subjects, whereas only 0.7% had asbestosis in the French cohort consistent with the importance of significant asbestos exposure and association with asbestos-related diseases.[47] The high prevalence of asbestosis in the Australian cohorts is consistent with greater asbestos exposure overwhelming the signal from pleural plaques as an independent risk factor.

Pathogenesis

Insight into the pathogenesis of malignant mesothelioma has come from experiments in which asbestos fibers were introduced into the pleural space of animals. These studies have demonstrated that amosite, anthophyllite, crocidolite, and Canadian chrysotile can all cause these pleural malignancies. Studies of fiber size in animals have shown that the most carcinogenic fibers are biopersistent, 0.1 to 1.0 μm in diameter, and more than 8 μm in length. Inspection of electron micrographs of asbestos fibers has shown that crocidolite and amosite possess needlelike characteristics, whereas anthophyllite has a more boxlike appearance and chrysotile has a long, curly appearance. These variations in size are also consistent with epidemiologic studies indicating that crocidolite and amosite may have greater risk for mesothelioma than do other types of asbestos. Becklake et al. have stated that there is a fiber gradient in toxicity, with chrysotile exhibiting lower toxicity than the amphiboles, and amosite exhibiting lower toxicity than crocidolite.[48]

One theory concerning the mechanism of asbestos-induced carcinogenesis focuses on the observation that asbestos fibers become entangled in the mitotic spindle during interphase, thereby causing chromosomal abnormalities. Electron microscopic evaluations have shown fibers penetrating between multiple lobes of the nucleus and associating, along their length, with the outer surface of the nuclear envelope. Structural chromosomal abnormalities in mesothelioma are clonal and complex and include both chromosomal gains (chromosome 22) and losses (chromosome 7). Deletions of the short arm of chromosome 3, the break point 1p11 to p22, chromosome 17, and structural and numeric changes in chromosome 7 have been described.[49] In asbestos insulators, sister chromatid exchanges in circulating lymphocytes are increased: larger chromosomes are more susceptible, and in the largest chromosome group, there is a significant interactive effect between asbestos exposure and cigarette smoking.

Cell lines established from malignant mesotheliomas have been shown to constitutively upregulate the PDGF B-chain gene and, to a lesser extent, the PDGF A-chain gene. High levels of transforming growth factor and IGF-1 bioactivity have been reported for cell lines derived from malignant mesotheliomas. These growth factors contribute to the considerable matrix formation that accompanies mesothelial tumors and promote mesothelioma cell proliferation.

Clinical and Radiographic Features

Pleural mesotheliomas are found mainly in males (ratio, between 3 and 4 to 1) and are most commonly diagnosed in patients between 50 and 70 years of age. Chest pain is the most common symptom experienced by patients with mesotheliomas. Dyspnea is next in frequency. Less common symptoms are cough, weight loss, and fever. A pleural effusion is usually present and can be massive. The effusion is an exudate, can be hemorrhagic, and may have high levels of hyaluronic acid (Fig. 85-6). Malignant mesothelioma is locally invasive, spreading along the pleural wall and invading the lung and nearby structures. Metastases are less common but can give rise to symptoms due to tumor in the diaphragm, heart, liver, spleen, adrenals, gastrointestinal tract, bone, pancreas, and kidneys. The paraneoplastic syndromes of inappropriate antidiuretic hormone secretion, clubbing, or hypoglycemia are reported. Thrombocytosis is common (90% in one series), and thromboembolic complications can occur. Ascites and weight loss are characteristic features of peritoneal mesothelioma.

A variety of radiographic abnormalities are found in malignant mesothelioma. They include a thick pleural peel along the lateral

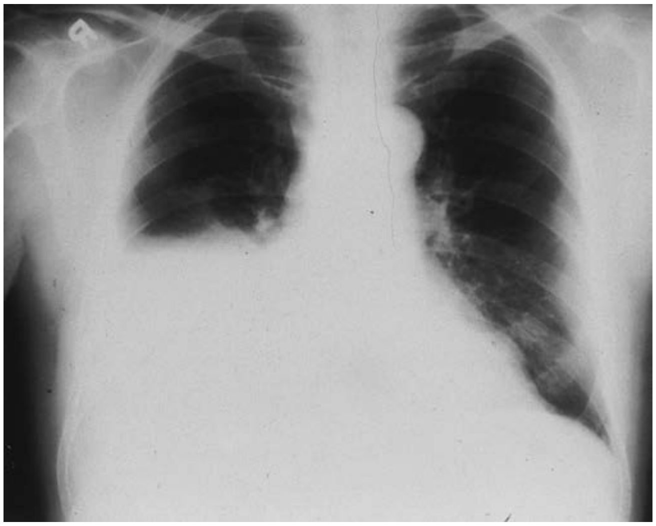

Figure 85-6 Large pleural effusion in an asbestos-exposed worker with an underlying malignant mesothelioma. *(Reproduced with permission from Dr. J. Elias.)*

chest wall that can extend to the apex with an irregular nodular surface, multiple pleural nodules or masses, plaque-like opacities, and pleural effusion(s). As the disease progresses, the lung parenchyma may be involved, the affected hemithorax may decrease in size, and the mediastinal or hilar nodes may be invaded. Pericardial thickening or effusion, abdominal extension, and chest wall invasion are common. The HRCT can help in differentiating pleural effusion from tumor and in determining the extent of tumor progression. The presence of asbestosis or of pleural plaques on the opposite side can assist in establishing the diagnosis of malignant mesothelioma.

■ Diagnosis

The diagnosis of malignant mesothelioma requires cytologic and immunohistologic validation. Calretinin, cytokeratin 5/6, and WT1 are the best positive markers for differentiating mesothelioma from pulmonary adenocarcinoma, and the best negative markers are TTF-1, CEA, MOC-31, and B72.3.[50] Obtaining a cytologic diagnosis from the pleural exudate is difficult because reactive mesothelial cells and malignant cells are not easy to distinguish. Biopsy is required. Because mesothelioma has been shown to invade the needle track, open biopsy is preferable. Thoracoscopy is the procedure of choice in establishing the diagnosis of mesothelioma.

Noninvasive biomarkers include plasma soluble mesothelin, osteopontin, and fibulin-3.[51,52] The receiver operating curve (ROC) for plasma fibulin-3 levels had a sensitivity of 96.7% and a specificity of 95.5% at a cutoff value of 52.8 ng of fibulin-3 per milliliter, and blinded validation revealed an area under the curve (AUC) of 0.87 for plasma specimens from 96 asbestos-exposed persons compared with 48 patients with mesothelioma. An AUC of 0.5 is no different between the groups, and an increased AUC greater than 0.7 is increasingly more sensitive toward 1.0, which is perfect sensitivity and specificity for the test in question. These blood tests can distinguish patients with malignant mesothelioma from asbestosis and pleural plaques as well as other causes of malignant pleural effusion such as lung and breast cancer.

■ Treatment and Prognosis

Median survival time is approximately 8 to 12 months for all patients with malignant mesothelioma. Overall, fewer than 10% of patients are alive at 5 years. Extrapleural pneumonectomy, combined with radiation therapy, may improve survival. Chemotherapy with gemcitabine and carboplatin or pemetrexed and cisplatin also may improve survival. Immunotherapy with intrapleural gene therapy with interferons has produced occasional complete or partial responses.[53–55] A promising area of research is intrapleural administration of adenoviral IFN-α2b, which resulted in tumor regression in five patients including one dramatic example of partial tumor regression at sites not in contiguity with vector infusion.[55] A detailed discussion of treatment options is provided in Chapter 78.

LUNG CANCER

In addition to mesothelioma, lung cancer is another well-recognized malignant complication of asbestos exposure.

■ Epidemiology

The association between asbestos exposure and the development of lung cancer was highlighted by Sir Richard Doll's 1955 epidemiologic cohort study of 113 men exposed to asbestos for 20 years, which reported 11 deaths due to lung cancer (compared with 0.8 expected).[56] All the individuals who died of lung cancer had evidence of asbestosis. In 1965, a retrospective cohort study in two asbestos insulator unions in the United States reported that deaths from lung cancer were 6.8 times the expected rate and that the incidence of lung cancer increased with time after exposure. In 1968, a follow-up of men in this cohort demonstrated an important synergy between asbestos exposure and cigarette smoking, since the risk of lung cancer was almost entirely borne by those who had a history of cigarette smoking.[57]

The largest survey of asbestos-related deaths evaluated a North American asbestos insulator cohort that reported a threefold excess of lung cancer deaths.[58] Comparatively few of these excess deaths were observed among those less than 25 years after the start of exposure. Lung cancer peaked at 30 years from exposure and mesothelioma at 45 years. In contrast, death rates from asbestosis increased progressively with time. This study confirmed the multiplicative effect of smoking plus asbestos exposure on the risk of lung cancer. Moreover, it showed that deaths from lung cancer dropped by almost two-thirds for asbestos insulators who subsequently stopped smoking. A recent follow-up of the North American insulator cohort from 1981 to 2008 found the following: 19% of the deaths were caused by lung cancer; the rate ratio of lung cancer in nonsmokers was 3.6 (95% CI, 1.7–7.6) and by asbestosis in nonsmokers was 7.40 (95% CI, 4.0–13.7); the joint effect of smoking and asbestos alone was additive (rate ratio, 14.4) and with asbestosis, supra-additive (rate ratio, 36.8).[59] Insulator lung cancer mortality halved within 10 years of smoking cessation and converged with that of never-smokers 30 years after smoking cessation.

Additional insights were provided by a study of amosite workers who were exposed to concentrations of 50 fibers per milliliter.[60] These patients experienced a fivefold increase in lung cancer. Long-term follow-up showed (1) a latency period of about 20 years before the increase in cancer occurred; (2) the greater the dose or the longer the exposure, the greater risk of developing lung cancer; and (3) the greater the dose or exposure time, the shorter the latency period before the tumor developed. Malignancies were also noted in the wives and children of these workers who were exposed to asbestos in the household, primarily on work clothes. In addition, men employed for less than 1 month between 1941 and 1945 developed lung cancer at an increased rate. Studies of a variety of other cohorts have confirmed the increased incidence of lung cancer in asbestos-exposed populations. They have also demonstrated an increased frequency of cancer of the larynx; in the latter, asbestos has been found in laryngeal tissue. As in the case of cancer of the lung, cigarette smoking has a strong association with the occurrence of these laryngeal malignancies.

Epidemiologic studies have also provided information about dose–response relationships and about the importance of asbestos-processing techniques and fiber type in the pathogenesis of pulmonary malignancies. The exposure–response relationship is considered to be approximately linear with higher level of lung cancer risk increment per fiber/mL-year for relatively low levels of asbestos exposure.[41,61] Differences in asbestos-processing techniques alter this relationship—for example, studies of a South Carolina plant demonstrated a steeper dose–response relationship in textile weavers versus chrysotile miners—probably due to the manufacturing process, which resulted in high levels of brief exposure during the opening of asbestos bags and the sudden separation of the asbestos fibers.[62] Similarly, differences in lung cancer mortality in asbestos cement product plants in Louisiana were found to be associated with the addition, in one of these plants, of crocidolite to the asbestos cement pipe mixture. The risk of lung cancer increases most clearly with cumulative asbestos exposure.

Pathology

Asbestos-related lung cancers are not distinct from lung cancers that occur in cigarette smokers and otherwise normal persons in type, nature, or location. All histologic types of lung cancer occur with increased frequency, but adenocarcinoma has the highest incidence. In the vast majority of patients, there is histologic evidence of asbestosis and asbestos bodies are frequently found. Asbestos-related lung cancer can occur in the absence of asbestosis.

Pathogenesis

Animal experiments using several types of asbestos have succeeded in reproducing pulmonary malignancies. In one study, approximately one-third of rats exposed by inhalation to asbestos (amosite, anthophyllite, crocidolite, Canadian chrysotile, or Rhodesian chrysotile) for periods ranging from 1 day to 24 months developed adenocarcinomas or squamous cell carcinomas of the lung.[63] In these experiments, a clear dose–response relationship existed between asbestos dose and the occurrence of tumors. In addition, available data indicate longer, thinner fibers having the strongest association with lung cancer, while fiber burden studies show that short fibers, especially chrysotile, are very frequently present.[41]

The mechanisms responsible for the induction of these malignancies include DNA adduct formation and poor repair, activation of nuclear transcription factors and driver cancer mutation, inhibition of tumor suppressor genes, reactive oxidant species, and chromosomal damage. The aldehydes acrolein and acetaldehyde are the predominant forces inducing DNA damage and inhibiting DNA repair using the TP53 gene in tobacco smoke carcinogenesis.[64] Crocidolite asbestos causes double-strand DNA breaks in small airway epithelial cells, which is the site for asbestos-induced fibrosis and carcinogenesis.[65] Reactive oxygen species also may play an important role in this process, since chrysotile asbestos, along with cigarette smoke, synergistically increases the number of breaks in DNA strands. Asbestos also induces nuclear factor-κB DNA binding in tracheal epithelial cells in vitro. NF-κB is an important transcription factor for cytokines, growth factors, and proto-oncogenes that could contribute in a variety of ways to malignant transformation. Alveolar macrophages also release TNF-α after phagocytosis of asbestos fibers, and TNF-α induces NF-κB in human mesothelial cells leading to increased survival (antiapoptosis).[66] These mesothelial cells exhibit increased mitotic index, and metaphases have prematurely separated chromatids or other chromatid abnormalities in in vitro cell culture.

The genomic understanding of early tumor development and progression has been further elucidated with deep next-generation sequencing of DNA extracted from adenocarcinoma in situ, minimally invasive adenocarcinomas, and fully invasive adenocarcinomas.[67] There were 21 of 347 cancer genes mutated among the 3 groups, and mutations in K-RAS, TP53, Jak-Stat, MAPK, cell cycle, and PI3K-AKT were found to increase in frequency from adenocarcinoma in situ to minimally to fully invasive adenocarcinoma. Deletion events were noted in chromosome 3p21 and 9q13, and KRAS and EGFR pathways were mutually exclusive, with the former pathway mainly seen in smokers. Yoshida et al. sequenced single cells from 632 bronchial epithelial colonies derived from bronchial brushings from children, never smokers, ex-smokers, and current smokers (n = 16).[68] They reported that current smokers' cells had a mean of 5300 mutations, ex-smokers 2230, never-smokers 290, and children 140 mutations per cell.[68] Smokers' genomes also had extensive insertions, deletions, and substitutions, and the number of mutations in different cells from the same individual could vary tenfold in smokers, a much higher variability than was found in nonsmokers. The most common smoking-dependent signature consisted of guanine-to-thymidine mutations, a signature that is characteristic of most smoking-associated lung cancers. In current smokers, at least 25% of cells carried driver mutations, including TP53 and NOTCH1, and specific TP53 mutations were found in multiple cells from the same individual suggesting that these mutations occur early. Driver mutations were double in smokers compared with ex-smokers and increased with age. Interestingly, in 5 of 6 ex-smokers, 20% to 50% of the cells had a low mutation burden that was similar to the profile of nonsmokers of the same age range. These cells had longer telomeres, suggesting they might have arisen comparatively recently from divisions of previously dormant stem cells.

Clinical Features

The patterns of presentation of lung cancer among asbestos workers are similar to those of high-risk patients: cough, chest pain, dyspnea, hemoptysis, recurrent bouts of pneumonia, and localized wheezing. However, patients can also be asymptomatic at the time of initial discovery, the abnormality being noted on a routine or screening CT scan. Other manifestations of carcinoma—such as rib invasion, shoulder–arm pain, and paraneoplastic syndromes—can also occur in asbestos-related malignancies.

Individuals with asbestosis have an increased risk of lung cancer.[69] Most patients with lung cancer in the Quebec asbestos mining district had small parenchymal opacities on the chest radiograph before death. In amphibole miners from South Africa with carcinoma of the lung who were evaluated by stepwise regression analysis for exposure variables, asbestosis was by far the most striking variable. Moreover, a dose–response relationship was found between the severity of asbestosis and the frequency of lung cancer. In the North American insulator cohort, 18% of the patients who died of lung cancer did not have radiographic evidence of parenchymal fibrosis.[70] Similarly, in a case control study of 271 patients with lung cancer, a small but definite increase in cancer risk was noted in patients whose chest radiographs were not definitely abnormal (0/1 or less).[71] This study indicated that asbestos exposures that do not cause small opacities on the chest radiograph may nevertheless increase the risk of lung cancer. Lung cancer mortality rate was 3.6 (95% CI, 1.7–7.6) times higher among long-term asbestos insulators who had never smoked and had no radiographic evidence of asbestosis compared with blue-collar controls; lung cancer risk doubles with asbestosis in smokers and nonsmokers among insulators.[41]

Radiographic Features

The radiographic manifestations of asbestos-induced lung cancers do not differ, per se, from those of lung cancers associated with other carcinogens. Mass lesions, atelectasis, post-obstructive pneumonia, and pleural effusions are all seen. As noted earlier, these lesions are frequently superimposed on a background of asbestosis or asbestos-induced pleural abnormalities. Confusion with lung cancer may arise from en face pleural plaques or rounded atelectasis. In contrast to lung cancer, however, these abnormalities are stable over time. The helical CT scan, which can evaluate the chest in a single breath, can increase the early detection rate of lung cancer in this high-risk patient population.

Diagnosis

The principles employed in the diagnosis of lung cancer in asbestos workers are identical to those in the diagnosis of pulmonary malignancies in patients exposed to other carcinogenic agents. Appropriate cytologic or histologic specimens are required. This can be accomplished by sputum analysis or by bronchoscopy with brushings, biopsy, or lavage. Transthoracic needle aspirates, thoracoscopic parenchymal biopsies, or open lung biopsies may be required for definitive diagnosis.

Treatment and Prognosis

The therapeutic approaches utilized for asbestos-related lung cancers are similar to those employed for lung cancers induced under other circumstances. When one is dealing with non–small-cell malignancies, patient operability and resectability need to be evaluated and, if appropriate, surgical extirpation undertaken. The impact of other asbestos-related pulmonary processes must always be taken into account. For example, severe asbestosis may limit operability, and diffuse pleural thickening may make surgical intervention problematic.

EFFORTS AT ASBESTOS CONTROL

In order to control the risk of exposure to asbestos, the Occupational Safety and Health Administration's Permissible Exposure Level not to be exceeded is 0.1 fiber/mL over an 8-h time-weighted average. As a public health measure and to protect children as well as workers, the United States should follow the rest of the world in banning the commercial use of asbestos.

Industrial hygiene efforts to control exposure have focused on engineering controls, including enclosure of the process lines, especially all sites where asbestos is introduced into a system, increasing ventilation, and the use of wet manufacturing methods. Personal respirators are used as a last resort in achieving control of exposure in the workplace; however, personal protective equipment including N95 or full-face respirators are required for removal of asbestos in place including demolition. Most of the insulation-manufacturing industry has switched to alternative materials, especially fibrous glass, rock and slag wool, and refractory ceramic fibers. Animal experiments have generally shown these asbestos substitutes to be safe, although refractory ceramic fibers have been shown to produce mesotheliomas in hamsters.

CONCLUSIONS

The asbestos-related diseases should be confined to history with the banning of asbestos in many countries and substitution of other insulating products. The Occupational Safety and Health Administration (OSHA) estimates that 2 to 3 excess lung cancers per 1000 workers exposed to the current standard of 0.1 fiber/mL for 45 years will occur and mandates work practices and engineering controls to lower exposure to asbestos. However, Nielsen et al. systematically reviewed the literature concluding that the increase in lung cancer risk was from 1% to 4% for each year of exposure to 1 fiber/mL (i.e., fiber/mL-year); we have the legacy of past exposures and the continuation of exposures during renovation and destruction of asbestos-containing buildings and products.[72] It continues to be an important area of compensation for workers developing mesothelioma, and for continued research on the mechanisms of fibrosis and carcinogenesis. Low-dose CT screening for asbestos-exposed workers can detect thoracic malignancies early and enable successful surgical treatment. The National Comprehensive Cancer Network recommends low-dose CT for people 50 years and older who have at least 20 pack-years of cigarette smoking and one additional risk for lung cancer, including occupational exposure to asbestos.[41]

Biomarkers for detection of lung cancer and mesothelioma are important for early diagnosis. Blood-based biomarkers based on plasma proteins ($n = 13$) have achieved negative predictive values of 90% in differentiating malignant nodules from benign.[73] Pathway analysis demonstrates that these proteins are involved in transcription regulators that are associated with cancer, lung inflammation, oxidative stress networks, and immunologic pathways. Gene panels and microRNAs can be differentiated in peripheral blood mononuclear cells or whole blood that are associated with lung cancer versus smokers with normal CT scans, and following surgery, the tumor influences are reversed.[74] Many of the genes that have altered expression in lung cancer are also found in the adjacent small-airway epithelium and proximal-airway epithelium consistent with an altered transcriptome in field carcinogenesis. Improving the performance of bronchoscopy with a bronchial brushing from the mainstem bronchus, a 23-gene classifier increased sensitivity to 96% in a series of 639 rule/out lung cancer patients achieving a receiver-operating-characteristic area under the curve of 0.78.[75]

Finally, the global control of asbestos should be a priority for international organizations since there is no further reason for asbestos to remain in commerce.

CHAPTER 86

Chronic Beryllium Disease and Hard-Metal Lung Diseases

Shweta Sood
Mary Elizabeth Kreider

INTRODUCTION TO BERYLLIUM

Beryllium is the lightest metal and has an atomic number of 4. Beryllium, as an element, was first discovered in 1798 by the French chemist Vauquelin and reduced to its metallic form. Subsequently, it was named beryllium in 1828 by the German metallurgist Wohler. Beryllium became a commercial product when it was used as an alloy first with aluminum and later with cooper, nickel, and cobalt after World War I. This commercial product was used in communications (telephones and telecommunication) and medicine (x-ray devices). The industry grew in the 1930s due to the increased use of beryllium–copper products during World War II in defense (military equipment), nuclear energy (nuclear reactors), and household items (fluorescent lamp industries).

With an increased industrial need for beryllium, acute chemical pneumonitis was first described by Weber and Engelhardt[1] in Germany in 1933 and in the United States by van Ordstrand et al. in 1943.[2] This condition was usually limited to the upper respiratory tract, although it could extend to the bronchi, bronchioli, and alveoli if there was sufficient exposure. The condition peaked in the 1940s. The last reported possible case in the United States occurred in the early 1980s. Acute pneumonitis due to beryllium is now rare and expected to be seen due to large-scale disasters such as beryllium plant explosions or other serious lapses in procedures.[3]

A second pulmonary complication of beryllium exposure was first described by Hardy and Tabershaw in 1946.[4] The disease differed from the acute chemical pneumonitis because of the delayed onset, granulomatous response, and chronic course. Now known as chronic beryllium disease (CBD), the condition is a hypersensitivity reaction, or sensitization to beryllium, and is the major hazard facing beryllium workers today.

In the modern era, acute manifestations of beryllium disease (such as acute pneumonitis) tend to be rare due to stricter governmental regulations that limit exposure in most developed countries. However, beryllium continues to be produced in high quantities in several countries, and exposure occurs in individuals working in select occupations, including primary beryllium factory workers, workers processing beryllium (foundry workers, furnace tenders, machinists, welders), individuals working with beryllium products (dental technicians, golf club manufacturers, bike parts manufacturers), and select industries (e.g., aerospace, automotive, defense, electronics, energy, telecommunications).[5,6] It is estimated that as many as 60,000 workers in the United States are still exposed to beryllium.[5,6] However, other studies suggest the prevalence of beryllium exposure is as high as 130,000 workers.[7]

Immunopathogenesis of CBD

There are three important characteristics of CBD.

First, this disease is usually associated with industrial exposure to beryllium. The only cases that have been described in nonindustrial workers have been in individuals who lived near beryllium plants and were exposed to the airborne emissions from the plant or from family members who brought contaminated work clothes into the home.[8,9] In addition, workers not directly handling beryllium may be exposed from processes occurring near them. A recent study showed that workers exposed to environmental concentrate dust from a nearby plant tested positive for beryllium sensitization at a higher-than-expected rate, suggesting that perhaps environmental factors in the absence of occupational exposure may play a role in the development of BeS.[10] The majority of cases have been described in individuals who have been involved in the heating, grinding, abrading, or handling of beryllium metals, alloys, salts, or oxides. Modern industrial hygienic practices include efforts to remove potential airborne beryllium at the source to prevent beryllium from becoming airborne, limiting the number of workers with potential exposure to beryllium, limiting skin exposure, and trying to keep the airborne levels as low as possible.[7] In 2017, updated Occupational Safety and Health Administration (OSHA) guidelines reduced the beryllium permissible exposure limit (PEL) to 0.2 μg/m^3 of air averaged over 8 h and set a new short-term exposure limit (STEL) of 2.0 μg/m^3 of air over a 15-min sampling period.[6,11]

A second important characteristic of CBD is the long time interval or latency that occurs between initial exposure and the onset of disease.[8] The average time to the onset of clinical symptoms is 10 years. This fact, combined with the lack of a clear-cut dose–response relationship to CBD, has hampered efforts to determine a safe level of beryllium. Thus, it is uncertain whether a peak exposure level or a total accumulated dose is more important for the development of CBD. Individuals have been described (e.g., secretaries with apparently little exposure) who have worked in industry for less than 1 year and yet still develop disease years to decades later.

A third important characteristic of CBD is that not all exposed workers will develop the disease. A minority of individuals exposed to beryllium will develop sensitization (estimated to be <20%).[12–14] Furthermore, only about 1% to 8% of exposed workers will ever develop the disease.[8,14] This percentage appears to have remained the same despite dramatic efforts by industry to reduce the potential exposure in their workers. The last characteristic of CBD is most likely due to a genetic predisposition.

The suspicion that an immunologic reaction to beryllium caused CBD was based on the following observations: (1) Beryllium painted on the skin (patch testing) could elicit delayed-type hypersensitivity reactions in patients with CBD.[15] However, because of the concern that patch testing could sensitize individuals to beryllium, skin testing has not been widely used. (2) CBD was associated with "immunologic granuloma." (3) Finally, animal studies demonstrated that a hypersensitivity could be demonstrated in animals and that this could be passed with cells.[16]

In vitro studies that simulated patch testing were developed in the 1970s and applied to patients with CBD.[17,18] The blood cells from a large percentage of patients with CBD had positive proliferative responses to beryllium. In addition, after stimulation with beryllium, blood cells from many patients with CBD could release a lymphokine: macrophage migration inhibition factor. However, all patients with CBD did not have positive responses with their blood cells.[19]

The confirmation that CBD was due to a cell-mediated response to beryllium came in the 1980s when cells harvested from the bronchoalveolar lavage fluid (BALF) from patients with CBD were examined.[20] There was a marked increase in the number and percentage of CD4+ T lymphocytes in the BALF noted. In addition, a positive proliferative response of bronchoalveolar lymphocytes to beryllium was observed. Positive proliferative responses to beryllium were observed in all cases of CBD, while negative responses were noted in beryllium workers with biopsy-proven, non-beryllium lung disease, patients with sarcoidosis and no history of beryllium exposure, and normal volunteers.[21,22] Notably, not only did all patients with CBD have a positive proliferative response of their bronchoalveolar cells to beryllium, the response was more pronounced in lung cells than in blood. The accumulation of beryllium-specific cells in the lungs of patients with CBD has been confirmed and shown to be due to effector memory T cells[23] that produce TH1 cytokines (interleukin 2 [IL-2], interferon γ [IFN-γ], tumor necrosis factor α [TNF-α]).[24,25] The T-cell response to beryllium is oligoclonal;[26] the response can be blocked by anti-HLA DP antibodies and requires the presence of HLA-DP2 antigen-presenting cells.[27]

Figure 86-1 Beryllium pathogenesis for CBD. Beryllium is inhaled and deposited in lungs. Antigen-presenting cells (APCs) present beryllium to T cells, triggering inflammatory response that can ultimately lead to granuloma formation over time.

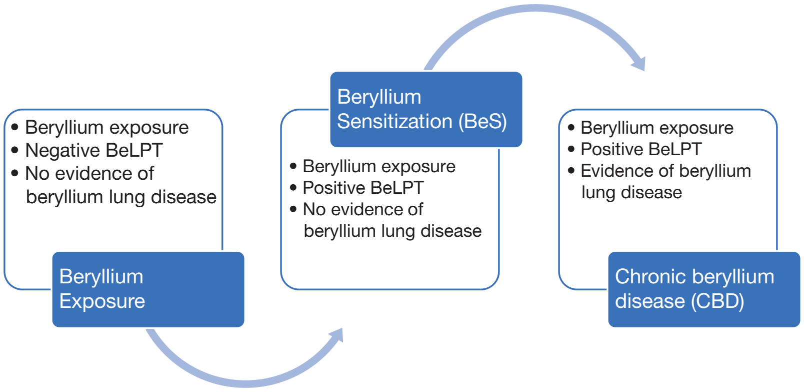
The CD4+ T-cell response to beryllium suggested that specific HLA class II molecules might be involved in CBD, since HLA class II molecules present antigenic peptides to CD4+ T cells. A strong association of CBD with the marker HLA DPB1-glu 69 was first shown by Richeldi et al.[28] and subsequently confirmed in three other laboratories.[29–31] However, rather than just a marker for CBD, this haplotype appears to be associated with the ability to develop an immune response to beryllium. The less frequent alleles that code for DPB1-glu 69 appear to be more associated with beryllium sensitization and disease than the more common alleles.[32,33] The crystal structure of HLA-DP2 has been solved and helps to explain the association with beryllium disease.[34] β Glu 69 lies in a pocket that is accessible to beryllium. In addition, two additional acidic amino acids, βGlu 26 and βGlu 68, lie in this pocket. Mutation of any one of these three amino acids eliminates the ability of the molecule to present beryllium to sensitized T cells.[35] A similar molecule on DR may be responsible for the development of beryllium sensitization in those who do not have HLA DPB1-glu 69.[32]

Additional genes probably account for the progression from beryllium sensitization to disease. Polymorphisms on a number of genes, including IL-1 A,[35] CC chemokine receptor 5,[36] NTNL2 in HLA-DPB1*Glu69 negative individuals,[37] and TGFb1[38] have been identified as a possible progression factor for the development of CBD. No association has been found with TNF-α promoter regions[39] or the TNF-α gene.[40]

The previously mentioned studies suggest the following model for the pathogenesis of CBD. Beryllium is inhaled and deposited in the periphery of the lung. Beryllium, either alone as a crystal or combined with a normal lung protein(s), is bound by glu 69–containing DPB1 molecules and presented to beryllium-specific T cells. The beryllium protein or beryllium crystal is poorly digestible and cannot be removed by the immune response. Persistent inflammation leads to granuloma formation. The cells of the granuloma secrete enzymes that cause tissue destruction and fibrosis (Fig. 86-1).[41]

■ Beryllium Exposure, Beryllium Sensitization, and Chronic Beryllium Disease

Recent clinical guidelines have emphasized the importance in distinguishing individuals with beryllium exposure from patients with beryllium sensitization (BeS) and chronic beryllium disease (CBD), as shown in Fig. 86-2.[42] Beryllium exposure typically occurs in individuals working with beryllium after inhalation or skin contact. In a select group of individuals, exposure can trigger a delayed hypersensitivity response called beryllium sensitization. Individuals with BeS develop an immune-specific response but do not have clinical evidence of lung disease. BeS is defined by a positive beryllium lymphocyte proliferation test, or BeLPT. A small group of patients with BeS can progress to developing clinical signs and symptoms of CBD.



• Beryllium exposure
• Negative BeLPT
• No evidence of beryllium lung disease
Beryllium Exposure
Beryllium Sensitization (BeS)
• Beryllium exposure
• Positive BeLPT
• No evidence of beryllium lung disease
• Beryllium exposure
• Positive BeLPT
• Evidence of beryllium lung disease
Chronic beryllium disease (CBD)

Figure 86-2 Distinguishing between beryllium exposure, beryllium sensitization (Bes), and chronic beryllium disease (CBD). In beryllium exposure, patients are not sensitized to beryllium (negative BeLPT) and have no evidence of beryllium disease. BeS is defined by a positive BeLPT but no evidence of lung disease. CBD patients tend to have exposure history, positive BeLPT, and clinical evidence of lung disease. Classically, CBD patients have granulomas on lung biopsies. In patients unable to undergo lung biopsy safely, a probable CBD diagnosis can be made using noninvasive testing (history, imaging, PFT, etc.) after other differential diagnoses have been excluded. BeLPT, beryllium lymphocyte proliferation test. It is suspected that only about 1% to 8% of exposed workers will ever develop the disease.

In contrast to individuals with BeS, patients with CBD develop both immune-specific response (a positive BeLPT test result) *and* clinical evidence of lung disease. The specific diagnostic tests for distinguishing BeS from CBD are discussed subsequently. Notably, management can be different for patients with beryllium exposure and sensitization compared to those with beryllium disease. Thus, understanding the features of beryllium exposure, BeS, and CBD is crucial for diagnosis and management.

■ Clinical Presentation of Chronic Beryllium Disease

CBD is primarily a pulmonary granulomatous disorder (Table 86-1). Although involvement of other organ systems has been reported (e.g., lymph node, skin, liver), the lungs are the principal organ affected and account for the morbidity and mortality of this disease.[43,44] Extrapulmonary manifestations of CBD have been reported but are rare. In the early stages, CBD may be asymptomatic or have mild pulmonary symptoms. A positive blood proliferative response to beryllium (a positive BeLPT test) may be the earliest sign of CBD.[12,45] Radiologic changes can be detected on routine chest imaging in asymptomatic individuals.

Symptomatic disease usually begins with nonspecific respiratory complaints, such as dyspnea and cough. Early in the disease process, routine chest radiography may not be helpful. Pulmonary function testing early in the disease may be normal or have an isolated abnormality of the diffusing capacity ($D_{L_{CO}}$).[46] As the disease progresses, symptoms become more characteristic for chronic interstitial lung disease (ILD) with a nonproductive cough, substernal burning pain, and progressive exertional dyspnea. At this stage dry bibasilar crackles can be observed on physical examination. A rare patient may have asthmatic-type complaints and physical findings.

With advanced disease progressive weakness, easy fatigability, dyspnea at rest, anorexia, and weight loss may occur, and acrocyanosis and clubbing may be observed. As cor pulmonale develops, peripheral edema, hepatomegaly, and distended neck veins are seen.[47] Fever is unusual but can be seen. Hypercalcemia and nephrocalcinosis, hyperuricemia, joint pains, and severe cachexia have been described. Severe liver involvement has not been seen, but liver granulomas with mild elevation of the liver function tests occur. Skin involvement may occur in 10% to 30% of cases and frequently involves small granulomatous nodules on the hands, arms, and chest.[43]

■ Radiography of Chronic Beryllium Disease

Radiographic changes in CBD are nonspecific and cannot be differentiated from sarcoidosis (Table 86-2 and Fig. 86-3). The most common radiographic abnormalities are diffuse round and reticular abnormalities.[48,49] While most patients have both round and reticular nodules, opacities may be only round or only reticular. These opacities are usually present diffusely throughout the lungs but may be confined to the upper lobes. Hilar adenopathy similar

TABLE 86-1 Clinical Features of Beryllium Exposure, Beryllium Sensitization, and Chronic Beryllium Disease[a]

	Beryllium Exposure or Beryllium Sensitization (BeS)	Chronic Beryllium Disease (CBD)
Clinical presentation	Usually asymptomatic	Non-specific. Can be asymptomatic in early stages. In later stages, can present with cough, dyspnea, chest pain tachycardia, tachypnea, crackles, hypoxia
PFTs	Usually normal	Nonspecific. Normal, restrictive, and obstructive patterns can all occur. $D_{L_{CO}}$ can be reduced or normal.
Imaging	Usually normal	Indistinguishable from sarcoidosis. Typically, mid-to-upper lobe nodules or fibrotic changes with lymphadenopathy. In early disease, thoracic imaging can also be normal.
Lung biopsy	Not necessary in almost all individuals since patients tend to be asymptomatic	Non-caseating granulomas indistinguishable from sarcoidosis[a]
Follow-up/ treatment	Avoid or limit beryllium exposure. Surveillance: Follow patients at least every 1–3 years.	Avoid or limit beryllium exposure. Surveillance for asymptomatic individuals: Follow patients at least annually. Treatment (usually steroids and/or steroid-sparing agents) can be considered for symptomatic patients.

[a] *The presence of a positive blood or BAL fluid BeLPT distinguishes chronic beryllium disease from sarcoidosis in patients with appropriate occupational exposure history.*

Data from Balmes JR, Abraham JL, Dweik RA, et al. An official American Thoracic Society statement: diagnosis and management of beryllium sensitivity and chronic beryllium disease. Am J Respir Crit Care Med. 2014;190(10):e34–e59.

to what is commonly observed in sarcoidosis may also be seen in up to 50% of cases. However, the large "potato type" node involvement is not seen. The computed tomographic appearance of CBD includes upper lobe or diffuse fibrosis, pulmonary nodularity, and hilar and mediastinal adenopathy. However, in biopsy-proven CBD the computed tomographic findings may be normal or demonstrate ground-glass changes.

As the disease advances, radiologic evidence of scarring and retraction can be seen. The hila are retracted upward, and conglomerate mass and emphysematous bullae may be present. Gross architectural distortion can occur from severe fibrosis. Pleural thickening can be seen in the presence of long-standing disease.

Radiographic changes can occur in CBD patients after therapy is initiated. In early disease, complete resolution of radiographic abnormalities can occur secondary to corticosteroid therapy and may recur as the corticosteroids are tapered.[50] Complete spontaneous disappearance of the radiographic lesions has not been observed.

Diagnosis of Chronic Beryllium Disease

A confirmed *definitive* diagnosis of CBD requires both demonstration of a granulomatous reaction on biopsy and evidence of

TABLE 86-2 Comparison of Chronic Beryllium Disease and Sarcoidosis

Manifestations	Sarcoidosis	Chronic Beryllium Disease
Erythema nodosum	10–20%	Absent
Hilar adenopathy	50–75%	<50%
Peripheral adenopathy	Occasional	Rare
Hypercalcemia	Occasional	Rare
Nephrocalcinosis	Rare	Rare
Bone changes	In chronic disease	Absent
Parotid involvement	Occasional	Absent
Posterior uveitis	Occasional	Absent
Liver involvement	Common	Frequent
Splenomegaly	Rare	Rare
Skin	Uncommon	Unusual
CNS	Occasional	Absent
Response to steroids	Only active disease	Only active disease

Figure 86-3 A 61-year-old male smoker who had worked at a beryllium processing facility for 20 years. He had a productive cough for 10 years but denied any shortness of breath. He had a positive response of both his blood and BAL cells to beryllium (stimulation index [SI] for blood beryllium lymphocyte proliferation test [BeLPT] = 13.8 [Nl < 3.0], SI for BAL BeLPT = 306 [Nl < 5.0]). His BAL also demonstrated a marked lymphocytosis (cell yield = 6 × 105 cells/mL [Nl < 3.0 × 105 cells/mL], lymphocytes = 55.2% [Nl <20%]). **A.** Chest radiograph demonstrating nodular interstitial disease with adenopathy. **B.** Chest CT mediastinal window demonstrating calcified bilateral hilar and mediastinal lymph nodes. **C.** Chest CT lung window demonstrating a diffuse fine nodular pattern of interstitial lung disease that was most prominent in the mid and upper lung zones.

beryllium hypersensitivity assessed via positive BeLPT on either bronchoalveolar lavage fluid or with a blood sample. In nearly all cases, transbronchial biopsy is sufficient to detect the presence of granulomatous inflammation characteristic in CBD and surgical lung biopsies are not needed. In some patients, bronchoscopy is not safe or feasible for several reasons including patient preference. Therefore, a diagnosis of *probable* CBD can be assigned to patients with a classic exposure history, positive blood BeLPT, and radiographic findings consistent with beryllium disease as long as other differential diagnoses can be excluded.[42] Select laboratories perform BeLPT including Cleveland Clinic Foundation (Cleveland, OH), National Jewish Center for Immunology and Respiratory Medicine (Denver, CO), and Oak Ridge Institute for Science and Education (Oak Ridge, TN). A positive BeLPT is defined in several ways: (1) two abnormal blood BeLPT, *or* (2) one abnormal blood BeLPT plus a borderline result for a blood BeLPT, *or* (3) one abnormal BAL BeLPT, *or* (4) positive skin patch test to beryllium (skin patch tests are rarely done in the modern era).

The sensitivity and specificity of BeLPT are estimated to be approximately 68% and 97% respectively.[42,51] In patients undergoing bronchoscopy, bronchoalveolar lavage fluid should be sent for cell count (lymphocytosis can be seen in CBD), cultures (bacterial, fungal, and mycobacterial to exclude infectious etiologies that can mimic CBD), BeLPT (a positive BeLPT result from BAL fluid can be present in patients with negative blood BeLPT result), and transbronchial biopsies from affected areas (to detect the presence of granulomas characteristically seen in CBD).

BeLPT in screening beryllium workers can be used.[42] Because immunologic tests of beryllium hypersensitivity have been available only since the late 1980s, their use for screening worker populations is not clear. However, studies to date indicate that blood proliferative response to beryllium is the most sensitive screening test for CBD. The major difficulty with using the blood proliferative response to beryllium as a screening tool is that not all individuals with beryllium sensitization go on to develop CBD. In addition, the number of workers with beryllium sensitization that ultimately develop symptomatic CBD that requires treatment also is unknown but may be relatively low and is probably less than 10%.[45]

The justification for a screening test requires that there must be some action that will alter the course of the disease. Although it is generally believed that early treatment of CBD will alter the natural course of this condition, this is not certain.[52] In addition, removal from further exposure, a prudent but unproven practice, is possible for current workers but would not be applicable to former workers. Thus, the strongest recommendation for use of the beryllium lymphocyte proliferation test as a screening test can be made for current workers. Recommendations for screening former workers and residents of communities with past beryllium exposure from the ambient air are less certain. Nevertheless, because the risk of developing CBD is lifelong, the question of appropriate screening for exposed individuals' remains unclear.

Differential Diagnosis for Chronic Beryllium Disease

The major challenge to making the diagnosis of CBD is to think of the possibility of beryllium exposure. Most cases of CBD that are misdiagnosed are diagnosed as sarcoidosis because either the exposure to beryllium was not known by the patient or the physician failed to elicit an occupational history. In 84 cases of sarcoidosis with a history of possible beryllium exposure, a final diagnosis of CBD was made in 34 with a mean delay from the diagnosis of sarcoidosis of 4 years.[53] A similar search for cases of beryllium disease in a cohort of sarcoidosis patients failed to identify any cases of beryllium disease.[54] Because the radiographic and clinical presentation of CBD (Table 86-2) is similar to sarcoidosis,[55] the differential diagnosis includes upper-lobe fibrotic processes (Table 86-3). In addition, as for sarcoidosis, other causes of granulomatous disease must be searched for and eliminated. The differential between sarcoidosis and CBD depends upon the result of the proliferation test to beryllium. Patients with sarcoidosis do not respond to blood proliferation to beryllium, while CBD patients do. A negative blood or BAL proliferation test can identify cases of sarcoidosis in those exposure to beryllium. However, caution should always be used, and repeatedly negative blood and lung tests should be determined before accepting a case of granulomatous lung disease in a beryllium worker as sarcoidosis.

Idiopathic pulmonary fibrosis

Treatment of Chronic Beryllium Disease

Treatment for chronic beryllium disease includes removing exposure, as well as corticosteroid and steroid-sparing agents. Small studies suggest that inhaled corticosteroids reduce symptoms but often do not improve pulmonary function test or radiographic findings.[56] No standard approach to the use of oral corticosteroids has been adopted in the treatment of CBD; however, guidelines suggest that a dose and duration mimicking treatment for sarcoidosis may be helpful (prednisone, 20–40 mg daily, followed by a taper to lowest tolerable dose over several weeks or months).[42,57–59] Because of the side effects, corticosteroids should be reserved for patients with documented pulmonary impairment or those with progressive deterioration. Doses of corticosteroids should be tapered to the lowest dose that controls the signs of active disease. Monitoring of patients with chest radiographs, pulmonary function tests, and exercise tests may be useful. Most cases of CBD are arrested with corticosteroid treatment. In cases of corticosteroid resistance or end-stage disease discovered at initial diagnosis, lung transplantation may be a reasonable approach.

Little data are available on the use of steroid sparing medications.[60] A trial of the anti–TNF-α antibody showed no significant clinical response in a very small cohort.[61] The long-term prognosis for CBD is uncertain. Follow-up of cases that were diagnosed in the 1940s and 1950s suggest that the mortality of the disease might be as high as 30%.[43] Whether a similar mortality will be present in patients with disease diagnosed since the 1990s is not certain. Newer techniques to diagnose CBD (immunologic testing) enable the disease to be detected earlier. The natural history of this condition detected at the presymptomatic stage is unknown. Two major remaining questions are whether disease that is detected early is inevitably progressive, and whether the disease will be responsive to corticosteroid therapy.

Beryllium and Lung Cancer

Many animal studies clearly indicated that beryllium is carcinogenic for several years. A National Institute for Occupational Safety and Health (NIOSH) study suggests that a small increase in lung cancer (SMR, 1.17)[62] may occur in beryllium workers. However, this finding has been challenged because of the poor data with regard to cigarette smoking.[63,64] This issue has remained controversial, however. In a report published in 2012, the International Agency for Research on Cancer stated that there was *sufficient evidence* in humans for the carcinogenicity of beryllium (Group 1).[65]

HARD-METAL LUNG DISEASE

Hard metal lung disease (HMLD) is a rare disorder that occurs in patients with exposure to hard metal. Hard metal is an alloy of tungsten carbide in a matrix of cobalt into which smaller amounts of other metals (chromium, molybdenum, nickel, niobium, tantalum, titanium, and/or vanadium) may be added. These components are milled to a fine powder, mixed together, pressed into the desired shape, and heated under pressure between 800° and 1000°C, yielding a product with a chalk-like consistency. The material may then undergo additional machining before being baked at 1500°C, which is above the melting point of cobalt and leads to the formation of an alloy. Once tungsten is intermixed with cobalt at high temperatures, the resulting metal has a hardness equivalent to $\sim$95% of diamond—hence the name "hard metal."[66] Because of this property, hard metal is an important component in cutting tools, drill bits, armor plate, jet engine parts, golf clubs, bike parts, and many other products.

Hard metal was developed in the 1920s, and ILD was first reported in hard-metal workers in 1940.[67] Lung disease has been noted to occur in those working in both the initial production of hard metal and the machining and maintenance of hard-metal tool components. In addition, although hard metal is not used in the diamond-polishing industry, a similar spectrum of disease has been reported in diamond polishers using steel polishing disks whose cutting surfaces consist of microdiamonds cemented into a fine cobalt mesh.[68] In contrast, workers in the cobalt-producing industry (who are more likely to be exposed to cobalt alone) may develop occupational asthma but appear to be much less likely to develop ILD. Cobalt lung disease has also been reported in individuals using e-cigarettes.[69]

The industrial processes associated with hard-metal lung disease produce respirable fine metallic dust particles. They also produce metallic ions that accumulate in the coolants used in the metalworking procedure and are absorbed through the skin or inhaled in vaporized coolant fluids. To counteract these exposures, the American Conference of Government Industrial Hygienists (ACGIH) has established current permissible exposure limits for cobalt metal, dust, and fumes at an 8-h threshold-weighted average (TWA) of 0.02 mg/m^3. NIOSH recommends an exposure limit of 0.05 mg/m^3 as a TWA for a 10-h workday and a 40-hour workweek, and OSHA requires an 8-h TWA of 0.1 mg/m^3.[70]

Clinical Manifestations in Hard Metal Lung Disease and Cobalt Disease

A variety of respiratory syndromes have been associated with exposure to hard metal, most commonly (1) asthmatic reactions, (2) a form of hypersensitivity lung disease, and (3) interstitial pulmonary fibrosis. The last two may be a continuum of the same process with subclinical or unrecognized hypersensitivity alveolitis proceeding to the development of fibrotic lung disease.

Over several decades, HMLD has been referred to as *hard metal pneumoconiosis*, *tungsten carbide pneumoconiosis*, *cobalt lung, and giant cell interstitial pneumonia.*[71] In the modern era, HMLD has been used to describe all types of lung disease, but it is most often used to reference the parenchymal or ILD, rather than the airway-related manifestations of hard-metal inhalations. While the nomenclature can be challenging, the key concepts to emphasize include the following: (1) hard metal is tungsten and cobalt mixed together; (2) only a select group of patients with exposure to cobalt or tungsten or both (exposure to hard metal) will develop lung disease for unclear reasons; (3) individuals with predominantly cobalt exposure may have markedly different symptoms than patients with predominantly tungsten exposure; (4) most studies suggest that workers exposed only to cobalt (no tungsten exposure) do *not* develop ILD but usually tend to develop airway-related disease or occupational asthma; (5) in contrast, workers exposed to tungsten (with or without cobalt) usually appear to develop ILD (Table 86-4).

TABLE 86-4 Comparison of Patients with HMLD and Primarily Cobalt or Tungsten[a] Exposure

Predominant Substance	Cobalt Alone	Tungsten (with or without Cobalt)
Typical Presentation	Workplace asthma type (cough, dyspnea, wheeze; symptoms may improve on non-work days)	Acute: Similar to pneumonitis (fever, cough, dyspnea, anorexia) Chronic: Mimics fibrotic ILD (chronic cough, dyspnea)
Diagnostic studies	Reduced peak flow. Positive bronchoprovocation test	Non-specific PFT and HRCT results; hence, occupational exposure history important. Pathology may reveal GIP.
Treatment	• Reduce workplace exposure • Bronchodilators • Inhaled corticosteroids • Oral corticosteroids rarely required	• Reduce workplace exposure • Often require oral corticosteroids

[a] *Patients with hard metal lung disease (HMLD) can have predominately cobalt exposure or tungsten exposure. Classically, HMLD is reserved for patients who develop ILD. Tungsten exposure seems to cause ILD more frequently. Cobalt-related lung disease is used to identify patients with asthma type of symptoms since ILD caused by cobalt disease is rare. (Cobalt ILD has been reported in very rare instances such as the diamond industry.) Since presentation varies between cobalt- and tungsten-related lung disease, diagnosis and treatment vary.*

Interstitial Lung Disease in Hard Metal Lung Disease

ILD has been seen in hard-metal workers. Studies have attempted to determine the prevalence of ILD among hard-metal workers. The studies have been frequently limited by lack of appropriate control groups, loss of former workers who may have left the plant due to illness, inconsistent disease detection/definitions, and small numbers. However, despite these limitations, it is clear that ILD develops in a small minority of exposed workers. Estimates range from 0.7% to 12.9% in cross-sectional studies.[72–77] A longitudinal study found no ILD in its cohort, but it was a small study with more recent exposure and may represent the effects of limiting exposure levels.[78] Reports of exposure intensity, duration, and immediacy have varied a great deal. For instance, in one review of 100 cases of HMD the duration of exposure varied from 1 to 30 years, and 1 case was diagnosed 40 years after a 3-year exposure had ceased.[79] Nonsmokers and former smokers also appear to be at higher risk.[80]

Interestingly, most studies suggest that workers exposed to cobalt alone without tungsten and other metals do not appear to develop ILD (Table 86-4). A few cases of diamond polishers exposed to cobalt alone who have developed ILD have been reported, but this appears to be fairly rare.[81] In some patients, HMLD presents as a hypersensitivity pneumonitis or allergic alveolitis. These patients manifest fever, anorexia, cough, dyspnea, inspiratory crackles, and fine reticulonodular infiltrates on chest radiograph. Pulmonary function testing typically shows a restrictive pattern, with a reduced DL_{CO}. Symptoms may resolve when exposure is discontinued but may recur with re-exposure.[82]

Over time, progressive dyspnea, lung function impairment, and interstitial fibrosis may develop. Fibrosis may also occur in the absence of antecedent symptoms. Patients with advanced disease exhibit weight loss, hypoxemia, digital clubbing, pulmonary hypertension, and cor pulmonale. The histopathologic manifestations of the interstitial disease in these patients can be varied, with findings consistent with bronchiolitis, desquamative interstitial pneumonitis, usual interstitial fibrosis, and giant-cell interstitial pneumonitis (GIP). Granuloma formation is infrequent. Lung biopsies may show heterogeneous patchy involvement with foci of active alveolitis, fibrosis, and normal parenchyma. Bronchiolitis may be seen in areas with and without active alveolitis. Infiltration with eosinophils also has been described. GIP is characterized by lymphoplasmacytic infiltration, epithelial desquamation, and the presence of numerous multinucleated giant cells in the alveolar spaces.[83] These giant cells are formed by both actively phagocytic alveolar macrophages and type II pneumocytes and are referred to as "cannibalistic giant cells." Notably, GIP has been seen in individuals without hard metal exposure; however, these cases appear to be rare.[84,85] At the present time, the presence of GIP in patients with hard metal exposure strongly suggests a diagnosis of HMLD.

Analysis of BALF may demonstrate hypercellularity with increased numbers of macrophages and giant cells. A relative or absolute increase in the number of lymphocytes with a reduced CD4/CD8 ratio, and increased numbers of neutrophils, eosinophils, and mast cells, also may be seen. In addition, the multinucleated giant cells can also be found in the BALF, which may be diagnostic of HMLD and obviate the need for a surgical lung biopsy.[86,87] One study found that a high number of eosinophils in the BAL that persisted after cessation of exposure and while on therapy was associated with a poorer outcome.[87] Electron microscopy with energy-dispersive x-ray analysis (EDAX) of the particulate material present in biopsy specimens may demonstrate the presence of the elements used to form hard metal. Because of its high solubility, significant amounts of cobalt are often not present.[79]

Naqvi et al. reviewed 100 cases of HMD identified either by the histologic presence of GIP or with a quantitative EDAX analysis containing tungsten at concentrations greater than 2×10^6 particles per cm^3 of lung tissues.[79] Of these, 59 had changes diagnostic of GIP. In more advanced cases, there were changes of end-stage fibrosis and honeycombing, with or without characteristic GIP lesions. Only 4 cases demonstrated granulomas, and of those, 2 also had changes of GIP. They examined 746 cases of ILDs examined by EDAX and found a striking correlation of tungsten with the finding of GIP, with higher levels of tungsten more likely to be associated with GIP. Cobalt was detected in only 36 patients in the larger cohort. Only those who had tungsten present in addition to cobalt had GIP findings on pathology. The investigators concluded that the presence or absence of cobalt was not useful in diagnosing or excluding HMLD.

Few studies have looked at the radiography of HMLD. Many of the screening studies of cobalt workers rely on plain chest radiographs and use the profusion score of the International Labour Office (ILO). However, a consistent description of the typical findings has not been offered. More recently, with the advent of computed tomography (CT) scans, a few case reports have described the CT findings of patients with HMLD. Like the pathology, these findings show a wide variability and can include end-stage honeycombing with cystic changes and traction bronchiectasis, to less impressive reticulation and even areas of ground-glass opacities.[88] No pathognomonic finding has been described.

Treatment for this disease consists of discontinuation of exposure and administration of systemic corticosteroids. A case report describes a patient who responded to a high dose of inhaled corticosteroids alone.[89] Although no clinical trials have been performed, dosage and duration of treatment similar to those used in other forms of active alveolitis or fibrosis should be considered. Patients with active alveolitis may show a dramatic response to steroids, whereas patients with more prominent fibrosis may show minimal response, despite prolonged steroid treatment.[66] Fibrosis may progress despite cessation of exposure. GIP has been observed to recur after lung transplantation, despite cessation of occupational exposure.[79,90,91]

■ Occupational Asthma in Cobalt Exposed Patients

In contradistinction from ILD, asthma can occur in workers exposed to cobalt alone without tungsten (Table 86-4).[92,93] The reported prevalence of asthma or wheezing related to cobalt or hard-metal exposure is low and ranges from 6.6% to 10.9%.[77,92,94] This variation may be attributed to different levels of exposure and the criteria used by various authors to define occupational asthma. As with other forms of occupational asthma, patients may note cough, wheezing, dyspnea, chest tightness, conjunctivitis, and rhinitis. Throughout the workday, symptoms may increase in severity, and a progressive decline in peak flow may be demonstrated. Symptoms usually abate during weekends or vacations and often resolve when exposure is discontinued.

Upper-airway symptoms may result from either direct airway irritation or atopic responses. In addition to demonstrating an association between workplace exposure and symptoms, the diagnosis may be confirmed by bronchoprovocation testing (BPT) with cobalt or cobalt salts. Testing with cobalt salts is preferable, as it is much easier to control dosage and delivery of soluble ion solutions than those of particulate substances. Immediate or delayed airway reactivity to cobalt chloride may be observed after BPT.[95] Tungsten carbide has not been shown to produce bronchoconstriction. A positive radioimmunosorbent test (RAST) to cobalt-conjugated human serum albumin also has been reported in some patients, suggesting a type I allergic response. Skin patch testing with cobalt salts does not appear to be of use in diagnosing hard-metal asthma.[95] Serum or urinary cobalt levels can be measured; however, false positives can be seen in smokers, patients taking multivitamins, or individuals with certain hip prosthesis. Furthermore, the cobalt levels may be elevated only for a short time after exposure.[71]

There is no clear dose-dependent relationship between cobalt exposure and spirometry abnormalities. Some studies have suggested a dose–response relationship between higher levels of cobalt exposures and lower forced expiratory volume in 1 s (FEV_1) on spirometry and symptoms of asthma.[77,93,96] A twofold increase in the relative odds ratio for work-related wheezing was noted when cobalt exposure exceeded 0.05 mg/m^3.[77] However, asthma and reductions in FEV_1 have been seen at levels below the allowable limit of 0.05 mg/m^3.[97,98] This suggests that the current permissible exposure limit may not protect all workers against the development of cobalt-induced asthma.

Since there is no direct link between exposure and asthma development in patients with cobalt exposure, baseline evaluations and employee screenings should be performed in workers exposed to hard-metal dust or cobalt alone. A reasonable strategy would include assessments for symptoms (rhinitis, conjunctivitis, wheezing, dyspnea, or chest tightness) and the relationship of symptoms to work hours, smoking history, physical examination, pulmonary function testing, and chest radiography. In patients with symptoms or findings suggestive of occupational asthma, peak flow monitoring during working and nonworking hours should be performed and other causes of pulmonary function deterioration ruled out.

Specific BPT and RAST results may provide additional positive criteria for diagnosis. Personal employee air sampling and measurement of urinary cobalt levels can provide information about ongoing exposure.[99] The workplace should also be examined for levels of cobalt exposure and employee protective practices. However, there may also be long-term respiratory health effects independent of the development of asthma. One recent longitudinal study found that those smokers with higher exposure had a greater fall in their FEV_1 over 10 years than those with less exposure. However, the contribution of the cobalt exposure to the overall expected decline was relatively modest (103 mL in addition to 518 mL from smoking alone in the highest exposure group).[78]

Treatment for occupational asthma related to cobalt includes control of exposure, as well as medical therapy with bronchodilators and inhaled corticosteroids. Systemic corticosteroid treatment is usually not required.[66]

■ Cobalt, Hard Metal, and Lung Cancer

Cobalt and cobalt-containing compounds have been shown to cause cancer in rats after local injection and intratracheal instillation.[100] Researchers reviewed the evidence for the carcinogenicity of cobalt in 1991 and concluded that although there was sufficient evidence for the carcinogenicity of cobalt metal powder and cobalt oxide in experimental animals, there was inadequate evidence for the carcinogenicity of cobalt and cobalt compounds in humans.[100]

Since that publication, however, there have been studies suggesting a relationship. One study of 709 French hard-metal workers found an excess of lung cancer mortality in their workers, and the excess was greater in workers with the highest levels of exposures although no relationship with duration of exposure was found.[101] However, this study was not powered to examine the effect of smoking as well, so firm conclusions could not be drawn. A second study by the same group of researchers found a twofold higher risk of lung cancer among subjects exposed to both tungsten and cobalt, and the odds ratio increased with cumulative exposure.[102] The study was able to adjust for smoking and found that the relationship between hard metal and lung cancer held.

A more recent study of one of the same plants was published in 2000 and examined mortality again from lung cancer with greater adjustment for smoking and exposure by job matrix.[103] Investigators found an elevated standardized mortality rate that increased with increasing duration, intensity, and cumulative dose of exposure to hard-metal dust. The excess was almost exclusively in subjects exposed to unsintered hard-metal dust. Ultimately, in a 2006 publication, the International Agency for Research on Cancer stated that cobalt with tungsten is *probably* carcinogenic to humans (Group 1A) and cobalt without tungsten is *possibly* carcinogenic to humans.[104]

■ Mechanisms of Injury in Hard Metal Lung Disease

The pathogenesis of the hard-metal–associated lung diseases is poorly understood. There are two predominant hypotheses for the pathogenesis of hard-metal lung toxicity: (1) hypersensitivity with lymphocyte-driven toxicity and (2) free-radical and cytokine-mediated injury.

Several authors point out the similarities of hard-metal lung disease and hypersensitivity lung disease, including the ability of cobalt to function as a hapten in complex with albumin and to cause a contact dermatitis.[105] BAL studies of both exposed workers and those with HMD have shown increased lymphocytes with reduction of the helper/suppressor T-cell ratios.[106] In addition, in at least one subject with HMD, a lymphocyte transformation test was found to be positive in the presence of cobalt.[107] Finally, a recent report suggests an association between a glutamic acid residue in position 69 of the HLA-DP beta chain and susceptibility to HMD.[108] This is similar to CBD, a known hypersensitivity disorder.

Notably, however, there are features of this disease that do not suggest a hypersensitivity reaction as the mechanism for the disease. Perhaps most obvious is the fact that granulomas, the hallmark of chronic hypersensitivity pneumonitis, are not typically found on biopsy. In addition, the finding that both cobalt and tungsten are required for most cases of hard-metal lung disease requires explanation. In vitro studies using peritoneal and alveolar macrophages from rats and mice have demonstrated that the combination of tungsten carbide and cobalt is highly cytotoxic, while cobalt and tungsten carbide alone produce minimal or no cytotoxicity.[109] In addition, the acute lung toxicity of tungsten carbide plus cobalt is much higher than that of each component after intratracheal instillation in rats.[110]

Lison[105] has proposed a mechanism that might explain this interaction. He suggests that tungsten carbide can act as an electron carrier to transfer electrons from cobalt to oxygen. This leads to the production of free radicals and reactive oxygen species, which, in turn, cause pulmonary damage. Differences in susceptibility to disease would, therefore, be due to differences in subjects' antioxidant defenses. Further research is required to elucidate the pathophysiology behind hard-metal lung disease.

SUMMARY

This chapter addresses two metals that cause lung injury usually due to an occupational exposure. Both beryllium and hard metal can cause interstitial pulmonary inflammation that is immune mediated. Beryllium results in a chronic cell-mediated response that is mediated by CD4+ T cells and results in granuloma formation. The mechanism of hard metal's interstitial inflammatory response is less clear but results in a giant-cell interstitial pneumonia, although other histopathologic findings can be seen. Both metals may cause disease in a minority of patients, and its development is not dose-dependent. Both metals have also been implicated in cancer. Chronic beryllium disease is indistinguishable from sarcoidosis unless a positive beryllium lymphocyte proliferation test is performed. Hard metal lung diseases may be associated with asthma-like reactions or interstitial lung disease. The presence of GIP on biopsy in patients with hard metal exposure is nearly diagnostic of HMLD. Improved diagnostic approaches to these conditions have resulted in earlier diagnosis and recognition of harmful workplace exposures.

CHAPTER 87

Coal Workers' Lung Diseases and Silicosis

Robert C. Stansbury
Rahul G. Sangani
John E. Parker

COAL WORKERS' LUNG DISEASES

Coal miners are at risk for developing several distinct clinical illnesses in relation to their occupational exposures. Historically, some names applied to these conditions were miners' asthma, phthisis, anthracosis, and in Scotland, miners' black lung. It was recognized early that these afflictions were related to the occupation of mining; however, it was not until the development of specialized techniques such as chest radiography, pulmonary function testing, the discovery of the tubercle bacillus, and sophisticated histologic examination of tissue that respiratory diseases affecting miners could be separated and defined. Advances in the understanding of respiratory health issues in coal miners have focused on the spectrum of disease caused by inhalation of coal mine dust, termed coal mine dust lung disease (CMDLD).[1]

CMDLD includes the classic occupational interstitial lung diseases, such as coal worker's pneumoconiosis (CWP), silicosis, mixed dust pneumoconiosis, and dust-related diffuse fibrosis (DDF).[1] CMDLD is a preventable occupational disease that results from inhalation of coal mine dust into the lungs leading to parenchymal and airway damage, from not only the foreign material itself but also the tissue's reaction to the dust.[1,2] This disease process was identified as early as the 1800s but became much more prevalent as coal production increased during the industrial revolution. Unfortunately, disability from coal mine dust exposure went mostly unrecognized by medical authorities in the United States through the first part of the 20th century. Congress finally passed comprehensive legislation with the Federal Coal Mine Health and Safety Act of 1969. This Act went above and beyond previous legislation by providing for the first mandatory standards for working conditions in U.S. mines, a system for enforcement, and ongoing monitoring of miner health, as well as a mechanism for seeking financial compensation for coal miners who could demonstrate total disability arising from their dust exposure (aka "black lung").[3]

Since the time of this landmark legislation, further acts by Congress and enforcement agencies have improved miners' working conditions, which now fall under the purview of the Mine Safety and Health Administration (MSHA). Much of our improved understanding of the nature and extent of lung disease associated with mining coal in the United States over the past half century comes from the large number of studies performed by the National Institute for Occupational Safety and Health (NIOSH). Despite increased understanding of CWP and reports of stable or improved dust levels in mines, dust-related respiratory disease remains a significant burden. Most worrisome are recent data suggesting that contemporary dust exposure is leading to rapidly progressive pneumoconiosis particularly in young miners, with a significant impact on pulmonary function and premature death.[4]

■ Coal and Coal Mining

Coal is not a pure mineral. It is a spectrum of carbonaceous rocks derived from the accumulation of vegetation sedimented under swampy conditions and subjected to extreme pressure over long periods of time. Coals are characterized by rank, which relates to geologic age, hardness, carbon content, and the amount of heat released (BTUs) when they are burned. Thus, peat is the lowest rank (softest) coal, being geologically the newest, and anthracite is the highest rank (hardest) and oldest type of coal.

Coal may be found in outcroppings and in seams that vary from a few feet to several thousand feet below the surface. Surface or strip mining, which currently accounts for the majority of U.S. coal production, involves removal of the overburden and mining the coal seams with large earth-moving equipment. In some areas of the eastern United States, mountaintop removal mining has become a dominant form of mining. Mountaintop mining involves first removal of all vegetation and soil, and then drilling and blasting through hundreds of feet of strata to access the coal seam. The excess rock and soil are placed in the steep stream beds along the mountainsides, creating areas called valley fills. Occasionally, surface mining is also performed by boring into coal outcrops with an auger. Dust levels measured in the air at surface mines have generally been lower than in underground mines, with a few notable exceptions, but miners who work exclusively at surface operations may still develop advanced forms of pneumoconiosis (discussed below).[5,6] Coal outcrops of sufficient size can be mined deep into the hillsides. Deep seams are accessed through vertical shafts drilled from the surface to the coal seam where the mining process then follows the seam through a series of more or less horizontal tunnels. Shaft drilling, which is frequently performed under contract for mine operators, may present an important silicosis hazard. A majority of the approximately 92,000 coal miners in the United States work at underground mines,[3] although deep mines produce somewhat less than half of the coal mined; in China, there are about six million underground miners.[1]

Respirable dust concentration, coal rank, types of mining work, mining category, and duration of exposure are known risk factors for the development of pneumoconiosis.[7] Dust exposure varies significantly between specific tasks within the mines. In underground mining, airborne dust is generally highest during work at the coal-cutting face, where coal is removed from intact seams. Miners involved in roof support (termed roof bolters; see Fig. 87-1), miners who do not use protective respiratory equipment, workers exposed to explosive blasting fumes, and those who use stored mine water for dust suppression spray are all at increased risk for accelerated loss of lung function.[8]

Many miners also have exposure to respirable crystalline silica, placing them at risk for silicosis and/or concurrent CWP/silicosis.[9] In particular, silicosis has been recognized among miners performing roof bolting and drilling operations, as well as motormen who operate underground coal trains and use sand for traction on the rails.[10,11] Workers in some aboveground coal mining operations also may have important exposure to dusts.[5,12] These include workers at tipples and preparation plants, where crushing, sizing, washing, and blending of coal is done, and coal is stored or loaded onto ships, railroad cars, or river barges. At surface coalmines, drilling rigs are used to bore holes in which explosives are placed. Equipment operators may be exposed to silica and silicate dusts from the rock strata, representing a risk for silicosis or mixed dust pneumoconiosis, rather than CWP (Fig. 87-1).

■ Epidemiology of Lung Diseases in U.S. Coal Miners

Results of radiographic surveillance from the 1970s through the mid-1990s showed a marked decline in the prevalence of CMDLD.[13,14] This decreased prevalence was a source of great optimism that

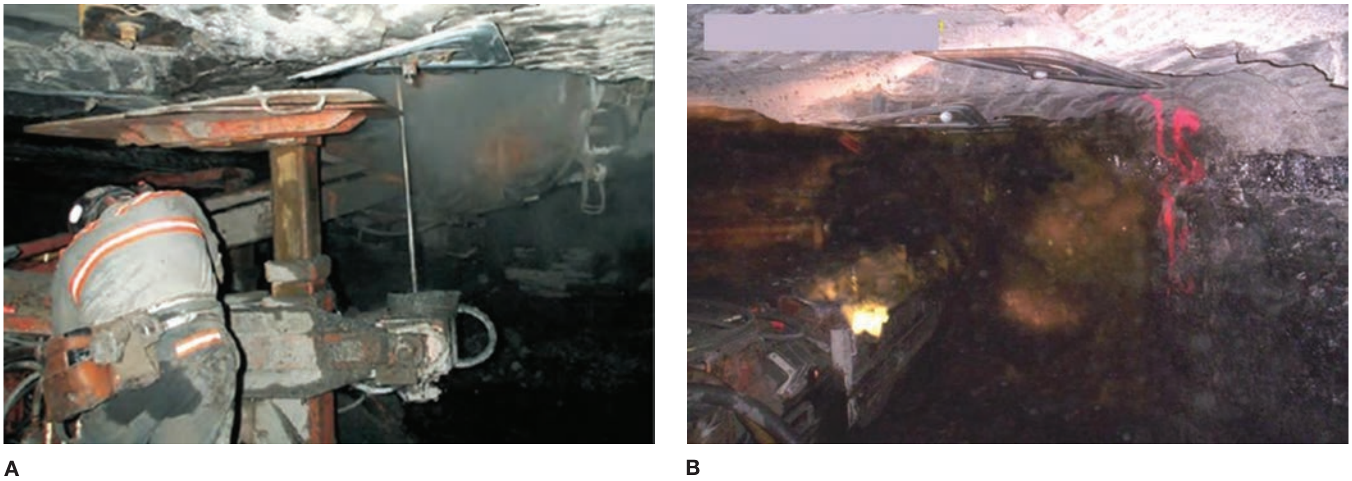

Figure 87-1 Photographs illustrating underground coal mining. In (**A**), miner is engaged in drilling before placing a roof bolt. In (**B**), the gray area above the black coal seam indicates where the mining equipment has pulverized a layer of silica-bearing rock. *(Reproduced with permission from Anita Wolfe, National Institute for Occupational Safety and Health, Morgantown, WV.)*

government regulations and oversight were resulting in improvement in miners' respiratory health. Often support for surveillance programs is decreased/eliminated when disease prevalence rates show such a significant decline. Fortunately for U.S. miners, continued work by institutions such as NIOSH have identified alarming changes in disease patterns (Fig. 87-2).[15] The most consequential findings of this contemporary work are the increased frequency and severity of disease in younger miners, higher prevalence rates of CMDLD, and a higher proportion of the most severe and often lethal form of CMDLD, progressive massive fibrosis (PMF).[16–18] In response to these trends the United States has lowered the permissible coal dust exposure limits (1.5 mg/m^3), expanded surveillance, and addressed several loopholes in dust sampling methodology.[19] While these interventions are promising, worrisome trends in miners' health remain and the efficacy of these interventions will not be apparent unless longitudinal surveillance programs are continued.[17,18] Despite a gradual shift into renewable energy, coal remains a critical source of energy production worldwide, accounting for 30% of global energy needs.[20] Coal mining employment in the United States and other countries around the world will remain high for years to come. Thus, continued surveillance by the public health sector and familiarity with the various manifestations of CMDLD by healthcare professionals will be necessary for miners' wellbeing through the 21st century.

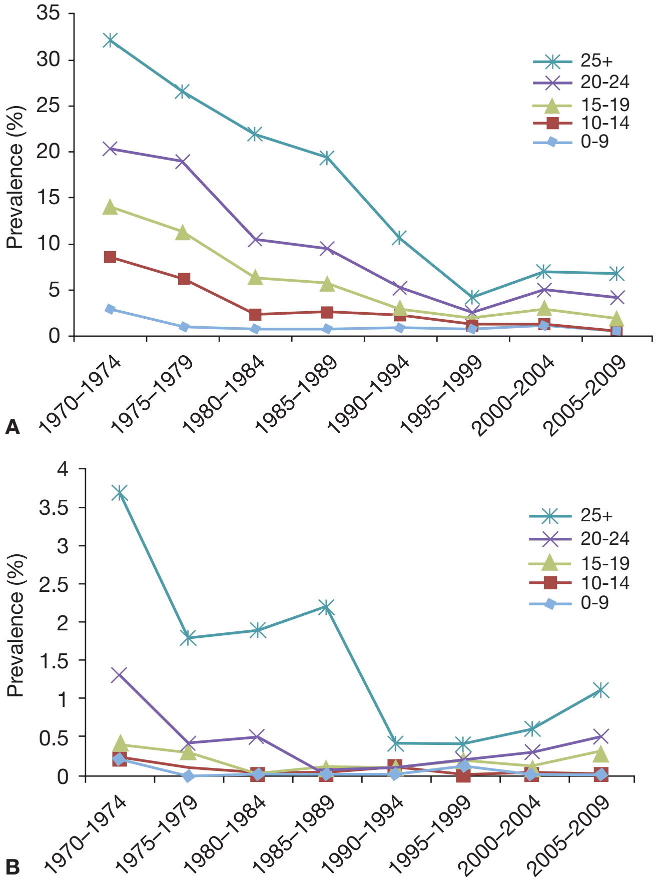

Figure 87-2 Proportion of miners examined in the NIOSH Coal Workers' X-ray Surveillance Program from 1970 to 2009 with coal workers' pneumoconiosis category 1 or greater (**A**) or progressive massive fibrosis (**B**), by tenure in underground coal mining. *(Reproduced with permission from Attfield MD. Centers for Disease Control and Prevention: Current Intelligence Bulletin 64: Coal Mine Dust Exposures and Associated Health Outcomes—A Review of Information Published Since 1995. DHHS (NIOSH) Publication No. 2011–172.)*

■ Radiographic Findings

Radiographic epidemiologic studies have been one of the cornerstones for surveillance of coal miners' health reported over the last four decades. As part of these activities, each miner's chest radiograph is independently interpreted by at least two qualified physicians, using the International Labour Office (ILO) pneumoconiosis classification system (Table 87-1).[21] Radiographic data from the initial health surveys showed an overall prevalence of simple and complicated CWP of nearly 30%. There was variation in prevalence by region of the country and the type (rank) of coal mined.[22] Enforcement of dust control measures in the United States, fully enacted in 1973, resulted in a declining pneumoconiosis attack rate. This decreased prevalence was confirmed through the federally mandated chest radiographic surveillance program for underground U.S. miners.[13,14] Between 1973 and 1978, CWP was found in about one-third of the miners who participated in the program and had worked 25 years or more underground.[14] By 1995 to 1999,

TABLE 87-1 Definitions of Terminology Used by the International Labour Office Classification to Describe Pneumoconiotic Opacities

ILO Term	Opacity Width	Opacity Type
P	≤1.5 mm	Small rounded
Q	1.5–3 mm	Small rounded
R	≥3–10 mm	Small rounded
S	≤1.5 mm	Linear/irregular
T	1.5–3 mm	Linear/irregular
U	≥3–10 mm	Linear/irregular
A	≥10–50 mm	Large
B	≥50–RUZ mm	Large
C	≥RUZ	Large

RUZ, Right upper (lung) zone.
Data from International Labour Office. Guidelines for the use of the ILO international classification of radiographs of pneumoconiosis. Revised edition 2011. Geneva, Switzerland: International Labour Office; 2011.

only 1 in 25 (4.2%) of these miners showed radiographic evidence of CWP.[14]

Regrettably, continued surveillance by NIOSH has revealed a continued increase in the prevalence of radiographic pneumoconiosis (to 10%) for miners with more than 25 years' tenure, since hitting its nadir around the turn of the century.[18] The rate of progressive massive fibrosis (PMF) has tripled to 1.1% after reaching its low point over a decade ago.[23]

Perhaps the most concerning findings of ongoing surveillance studies have been the frequency of rapidly progressive radiographic disease in certain mining populations. During their 2005 analysis, Antao et al. found that in miners with pneumoconiosis, about 35% had rapidly progressive disease. This rapid progression was defined as an increase of greater than one ILO subcategory over 5 years.[24] More worrisome is the fact that 15% developed PMF, the most advanced and debilitating form of the disease. By 2015, the prevalence of PMF in Central Appalachia reached the highest levels ever recorded.[25]

Radiographic analysis has been complemented by ventilatory lung function testing as an integral component of respiratory health studies of the mining population. Early reports strived to identify a relationship between radiographic disease and spirometry results. Multiple studies in the United States and abroad have subsequently evaluated the relationship between radiographically evident CMDLD and lung function.[26–28] Although several earlier studies did not associate lung function impairment with uncomplicated CWP, recent analysis has identified significant ventilatory deficits among coal miners with small radiographic opacities, in addition to the important decrements in lung function that have been observed in miners with the large radiographic shadows (>10 mm) of PMF.[4,28,29]

Studies in the United States and Great Britain evaluated lung function with respect to the miners' cumulative dust exposure and have helped to clarify the adverse effect of dust on coal miners' lung function.[30–32] Miners show a progressively greater risk of lung function loss with increasing cumulative dust exposure, independent of the chest radiographic findings of CWP. The forced expiratory volume in 1 s (FEV_1) loss is most severe in those who work for many years at the dustiest jobs. Among smoking miners, the effects of tobacco smoke appear to be additive and of similar magnitude to the dust effect. Studies of FEV_1 decline have demonstrated essential equivalence between 1 year of work in a job at the coal face and 1 year of cigarette smoking: no disproportionate dust effect has been noted in relation to tobacco use. Also, there is evidence that miners experience a more rapid loss in spirometric function parameters during their first few years of mining, with slower dust-related declines after that time.[25]

In summary, the epidemiologic evidence has shown that coal miners experience ventilatory lung function loss with increasing exposure to dust, in the presence or absence of radiographic CWP. Among smoking miners, the effects of tobacco and dust appear to be additive. Although, on average, the functional losses associated with either dust or smoking are small, it is estimated that after 35 years of work at the current permissible limit, dust exposures will cause a clinically important FEV_1 loss in 8 out of 100 nonsmoking coal miners. Higher exposures result in greater losses. When chronic bronchitis is present, there is an additional FEV_1 reduction averaging 200 to 250 mL.[7,33] With simple CWP, and especially when PMF is present, an additional ventilatory deficit is likely.

Investigations into miner mortality have been completed in both the United States and Britain. Findings from both countries have been generally consistent and reveal that the miners experience increased mortality attributable to pneumoconiosis, emphysema, chronic bronchitis, and ischemic heart disease.[34–39] Radiographic findings of advanced CWP (PMF) consistently affect mortality, especially in categories B and C (see Table 87-1 for definition of ILO terminology), whereas among miners with simple CWP, decreases in survival were smaller. Accelerated FEV_1 decline is also associated with increased mortality from both cardiovascular and respiratory causes.[36] Miners' risks of dying from the obstructive airway diseases of emphysema and chronic bronchitis exhibit a different geographic pattern than the mortality from CWP, suggesting that these dust effects have different mechanisms.[37] Attfield and Kuempel[38] analyzed the mortality experience over 22 to 24 years among 8899 working coal miners. Their results revealed increased mortality from nonviolent causes, nonmalignant respiratory disease, and accidents, and confirmed previous results indicating that exposure to coal mine dust leads to increased mortality in the absence of tobacco smoke exposure.

Troubling recent data regarding miners with both rapidly declining lung function and rapid progression of radiographic disease seem to have had mortality implications as well. A NIOSH report from 2018 revealed a substantial increase in years of potential life lost (YPLL) attributable to CWP between 1996 and 2016.[40] A study in 2011 reviewed a decade of data (at current exposure levels). Investigators found rapidly progressive pneumoconiosis and massive fibrosis in relatively young West Virginia coal miners that led not only to important lung dysfunction but also to premature death.[4] More documentation for the high risk of contemporary coal mine exposures comes from investigations into mining accidents. Lung tissue analysis was performed on 24 victims of a recent mine explosion. Of the 24 victims, 17 (71%) had autopsy evidence of CMDLD; 16 of the 17 miners with CWP had started working after the modern dust limits were put into effect.[41] Unfortunately these concerning trends continue, particularly in Appalachia.[42] The implications of these new studies are incompletely understood, but it is obvious that contemporary miners are still developing severe and fatal CMDLD.

Pathology of Coal Miners' Lung Diseases

Heppleston[43] identified the coal macule as a fundamental histopathologic finding in CMDLD in 1953 (Fig. 87-3). In his discussion, he described the macule as consisting of a focal collection of coal dust in pigment-laden macrophages around the respiratory bronchioles and tapering off toward the alveolar duct. A fine network of reticulin is present in the early stages and may include

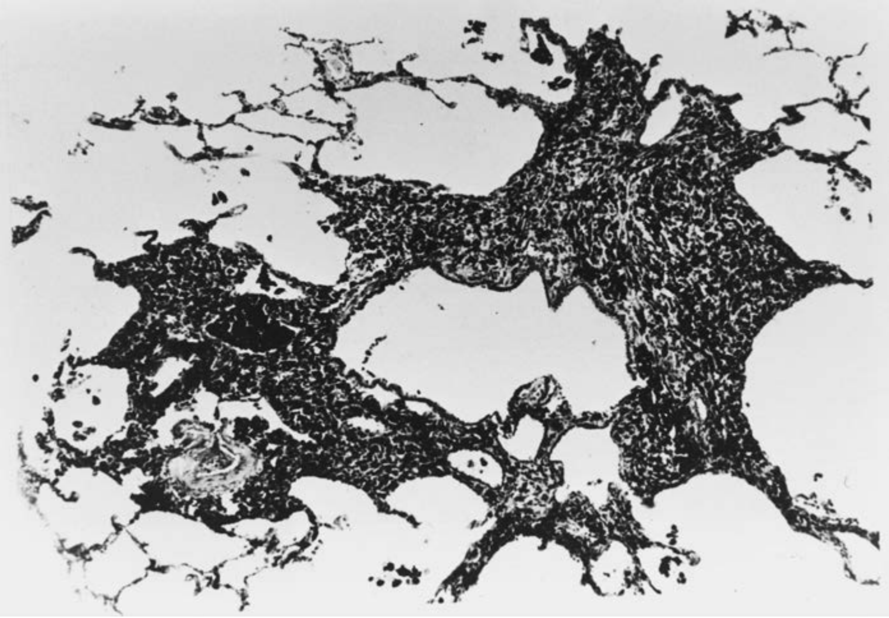

Figure 87-3 A coal macule, microscopic section. *(Reproduced with permission from Dr. Val Vallyathan, National Institute for Occupational Safety and Health, Morgantown, WV.)*

a small amount of collagen depending upon the character of the dust.[44] Centriacinar emphysema, the dilation and injury of lung gas exchange units, is observed with increased prevalence in the lungs of coal miners. Focal emphysema is the form of centriacinar emphysema that is seen as an integral part of the lesion of simple CWP. It is characterized by enlargement of the airspaces immediately adjacent to the dust macule. The pathologic severity of the emphysema is proportional to the miner's cumulative dust exposure and increases with increasing lung dust retention.[45–47] Muscular thickening of pulmonary arteries, in conjunction with hypertrophy of the right ventricle, can be observed with both simple and complicated CWP and is increasingly prominent when CWP is associated with other lung disorders.[48] The development of pulmonary hypertension secondary to these changes may have a profound adverse effect on miner mortality.[49] Pathologic changes in the airways consistent with chronic bronchitis, including enlargement of mucus glands, have also been documented in miners' lungs.[50]

Central to the biology of CMDLD (discussed below) is the alveolar macrophage.[51–53] Dust particles that travel to the distal airways (beyond the mucociliary escalator) are engulfed by alveolar macrophages and removed from the airways and lung parenchyma via lymphatics. With extended excessive dust exposure, this system is overwhelmed and coal mine dusts as well as dust-laden macrophages begin to accumulate in the airway walls and interstitium. Recent evidence suggests that important lung functional losses observed during coal mining work may at least in part be related to this dust reaction in the small airways.[54–56] With ongoing dust deposition and inadequate clearance mechanisms, these lung lesions increase in size and number. These larger fibrotic lesions are called coal nodules and are palpable in lung specimens, whereas coal macules are not. Palpable coal nodules are classified as micronodular up to 7 mm in diameter and macronodular from 7 mm and larger.[57]

A less common form of CMDLD and silicosis labeled DDF has been increasingly recognized. This finding had previously been interpreted as representing the development of usual interstitial pneumonitis (UIP) in miners. Recognition of a pulmonary fibrosis pattern related to CMDLD has been supported by case reports and several studies.[58–60] In their position paper the Industrial Injuries Advisory Council (IIAC) found "there is good evidence for a form of interstitial fibrosis which is really part of the disease process of CWP and is not typical of cases of interstitial fibrosis in noncoal workers." DDF has been described in pathologic terms as a bridging fibrosis connecting various stages of CMDLD lesions and/or lesions of silicosis and has been found in approximately 12% of coal miners at autopsy.[61] An occupational history is of utmost importance to the proper clinical recognition of DDF as opposed to UIP.[62] This distinction is of importance both from a prognostic and management standpoint.

At autopsy, complicated CWP (PMF) is confirmed when one or more nodules in a lung specimen are noted to attain a size of 2 cm or greater in diameter.[57] The 2 cm is an arbitrary choice of a minimal diameter that permits better correlation with clinical and radiographic measurements. (In fact, when radiographic pneumoconiotic shadows are >1 cm, PMF is said to be present.) Lesions are solid, heavily pigmented, and rubbery to hard. They tend to occur symmetrically, but they may be asymmetrical and may cavitate.[61,62] Airways and vessels adjacent to the lesions may be distorted, and within the lesions, they are destroyed. PMF generally occurs in association with background pathologic changes of simple CWP.[63]

■ Biology of Coal Workers' Pneumoconiosis

Numerous studies have evaluated the relationship of coal mine dust exposure and activation of immunologic and inflammatory mechanisms. Soutar et al.[64] reported a study of serum antinuclear antibodies (ANA) and rheumatoid factor (RF) among 109 miners with radiographic evidence of pneumoconiosis attending the London Pneumoconiosis Panel. They reported positive ANA in 17% and RF in 10% of the miners, whereas about 2% to 3% positive ANA was expected in a healthy male population. The prevalence of ANA was 9% in simple CWP and 27% in those with category C (PMF). A similar trend was seen with RF, ranging from 6% in simple CWP to 18% in category C. Combining both ANA and RF resulted in positive results in 13% of the miners with simple CWP and 45% of those with category C CWP.

Studies of serum immunoglobulins were conducted by Hahon et al.[65] among 155 U.S. coal miners with chest radiographs demonstrating simple CWP, Caplan syndrome (an atypical clinical presentation of pneumoconiosis associated with features of rheumatoid arthritis), or PMF. Among miners with PMF, those mining anthracite coal had significantly higher serum concentrations of C3, α1-antitrypsin, IgA, and IgG compared with miners from bituminous regions. Compared to normal controls, the miners had elevated C3,

α1-antitrypsin, and IgG values. There were few differences in these serum proteins among the miners with simple CWP. The authors did not find any association between the elevated immunoglobulins and FEV_1.

Significant research has been undertaken to understand the biologic mechanism(s) of CMDLD. Compared to controls, miners with CMDLD have been shown to have elevations in both serum and bronchoalveolar lavage (BAL) levels of several cytokines, which play an important role in lung inflammation and fibrosis, including IL-1β, IL-6, and TNF-α.[66,67] Inflammation resulting from oxidative stress has also been suggested in both human and animal data.[68,69] One potential contributor to miners' increased oxidative stress is the level of bioavailable iron. Iron has the known potential to catalyze oxidant formation through its interaction with oxygen or hydrogen peroxide. The potential of bioavailable iron to induce oxidative stress has been associated ecologically with regional variations of CMDLD prevalence.[70]

Although immunomodulation and inflammation play an important role in the development of CMDLD, the underlying host susceptibilities that lead one miner to develop severe disease in a given environment while another miner may have a relatively minimal disease burden remain elusive. Genetic studies have been unable to confirm specific markers of susceptibility to CMDLD. Small studies have suggested that certain polymorphisms including those involving IL-18 may be protective.[71–73] A recent study in Chinese miners suggests that single nucleotide polymorphisms in the H19 gene are correlated with a decreased risk of CWP.[74] Continued studies on the mechanisms of CMDLD and understanding of disease susceptibility are important, given recent trends in CMDLD epidemiology.

■ Clinical Features of Coal Workers' Lung Diseases

Reflecting the diverse lung pathology associated with coal mine dust exposure, it is not surprising that the clinical presentation of the disease may be quite variable. Miners with simple CWP, perhaps detected through a screening radiograph, may deny significant respiratory symptoms. With increased dust exposures, chronic cough and sputum production are more common, regardless of the presence or absence of simple pneumoconiosis.[75] These symptoms are likely related to bronchitic changes in the large airways, including thickening of the airway wall with mucus gland enlargement and hypersecretion that result from continued inhalation of dust particles presenting a chronic burden to the mucociliary escalator.[50,76] A study by Henneberger and Attfield[77] reported symptoms of chronic bronchitis in 35% of seasoned U.S. miners.

Emphysema has been shown to be more common in miners than nonminers, even after controlling for smoking status, and increases with increasing cumulative dust exposure.[45] As would be expected, with more severe airflow obstruction or advanced pneumoconiosis, dyspnea, cough, and sputum production are frequent. The physiologic importance of the small airway lesions from dust exposure has been debated. A pathologic label of mineral dust–related airway disease has been used to describe a lesion of pigmentation and fibrosis specific to walls of the respiratory bronchioles among workers exposed to mineral dusts.[78]

Less commonly, edema of the lower extremities, and findings consistent with cor pulmonale/pulmonary hypertension, may occur.[48,49,78] An exceedingly rare but unique clinical manifestation of CMDLD is melanoptysis (expectoration of black sputum). Melanoptysis may be a very worrisome symptom for patients but is the harmless result of excavation and liquefaction of a PMF lesion.[80]

Clubbing and crackles have not generally been considered features of coal miners' lung diseases and, if noted, should prompt further studies. For instance, a case series of 38 miners described atypical findings including crackles, finger clubbing, restrictive impairment, diffusion block, and neutrophilic BAL. Ultimately these miners were found to have chronic interstitial pneumonia.[81] Studies have not associated CWP with an increased risk for development of coexisting mycobacterial infection, in contrast to silicosis, where the risk is well documented. However, in a minority of coal miners, the lungs show classic silicotic nodules.[82] Certainly, coal miners with progressive infiltrates or cavitary lesions in PMF should undergo thorough sputum examination for typical and atypical mycobacteria.[83]

■ Radiology of Coal Workers' Pneumoconiosis

The diagnosis of CWP can be made with confidence based on the classic radiographic findings and the presence of an adequate history (at least 10 years) of coal mine dust exposure without the need for histologic confirmation.[1] The radiographic opacities of CMDLD have been well described and are classified according to the ILO system.[21] This system includes a set of standard radiographs, which can facilitate an accurate and consistent approach to recognizing and categorizing the radiographic changes associated with dust exposure. Traditionally analog chest films were used in the classification scheme. This practice changed in 2011 to include classification of digitally acquired images on a high-resolution medical viewing system.[84] Digital systems can provide equivalent results in the recognition and classification of the pneumoconioses when applied according to professional recommendations.[84,85] The radiograph in simple pneumoconiosis shows small pneumoconiotic opacities, ranging in size from pinhead up to 9 mm in diameter. In a study of working U.S. coal miners with radiographic small opacities, 62% showed mainly rounded small opacities while 38% had predominantly irregular opacities.[86] Irregular opacities were more common in lower lung zones. PMF is characterized by one or more opacities in the lung fields greater than 1 cm. Complicated pneumoconiosis is more commonly seen in the upper lung zones, but is confined to the middle and/or lower zones in about one-fourth of cases.[87,88] Although there are some limitations to the use of standard posteroanterior CXR in the diagnosis of simple CWP and of PMF, standard radiographic evaluation of CMDLD remains important for diagnosis, surveillance, compensation, and disease prevention.[82]

Computed tomography (CT) scanning in coal miners may reveal parenchymal nodules and emphysema when standard radiographs are normal.[89,90] In atypical cases, CT scans may show ground-glass opacities and honeycombing, at times without nodular findings typical of CWP.[91] Radiographic evidence of bronchiectasis has also been reported in coal miners, particularly among those with CWP.[92] CT scanning is currently not recommended in the surveillance of exposed miners, but it is likely of use in symptomatic miners with normal plain chest radiography or in miners where alternate diagnoses are being considered.[93] A pneumoconiosis classification scheme for CT has shown good reliability but has yet to be widely adopted.[94]

Several schemes have been used for classifying the radiographic shadows of pneumoconiosis in epidemiologic studies; currently the ILO 2011 Classification of Radiographs of the Pneumoconioses is the most widely accepted (Table 87-1).[21] When using the ILO system, simple pneumoconiosis is divided into major categories 0, 1, 2, and 3 according to the profusion of small opacities (number per unit area) in the lung fields. Each major category, including 0, is subdivided into 3 subcategories, providing a full range of 12 categories of simple CWP. A reading of category 1/0 indicates the definite presence of opacities consistent with pneumoconiosis. Complicated pneumoconiosis (PMF) is divided into categories A, B, and C, based on the size of the large opacities. The classification also permits documentation of other findings that may be associated with the shadows of simple or complicated pneumoconiosis, such as tuberculosis, cor pulmonale, collapse, consolidation, and emphysema. A system of training and examinations (*www.cdc.gov/niosh/topics/chestradiography/breader.html*) is available for physicians who wish to document competence in application of the ILO Classification.

The clinician may be presented with the diagnostic dilemma of distinguishing primary or metastatic lung neoplasia from an unusual presentation of PMF or Caplan syndrome. When typical large opacities of PMF occur symmetrically and bilaterally on a background of simple CWP, one can be confident that the lesions are unlikely to represent neoplastic disease. Prior radiographs from medical screening programs are often obtainable and can help confirm stability or progression over a long time interval. Positron emission tomography with fluorodeoxyglucose (FDG-PET) scanning may be useful in differentiating PMF lesions from malignancy when the mass lesion has a low level of glucose metabolism, although some massive pneumoconiotic lesions may demonstrate an uptake of fluorodeoxyglucose similar to neoplasms.[95] On magnetic resonance imaging (MRI) with contrast enhancement, the pattern of change over time in signal intensity has been reported to be a differential criterion in this setting.[95,96] When the imaging workup is equivocal, the differentiation of PMF from neoplasm may be impossible without a biopsy. In this case, patients with CMDLD who are deemed potential candidates for therapy should undergo biopsy of the suspicious lesion. Hemorrhagic complications may occur during biopsy of PMF lesions due to their vascular nature.

■ Lung Function and Respiratory Impairment in Coal Miners

As discussed earlier, CMDLD encompasses a spectrum of diseases caused by inhalation of coal mine dust that results in several pathologic processes (simple and complicated CWP, silicosis, DDF, chronic bronchitis, mineral dust airway disease, emphysema, and dust-related airflow limitation), each of which may contribute to adverse physiologic consequences. In an individual miner, the pattern and severity of impairment found will be related to such recognized factors as the intensity and duration of respirable dust exposure, geologic factors (e.g., coal rank, silica content), residence time of dust in the lung, and exposure to other respiratory hazards (e.g., tobacco smoke).[7,8,26–33,37] In miners with airway hyperresponsiveness, greater functional deficits and an increased risk of symptoms may be expected.[97,98] Several other mining exposures may also contribute to lung function loss in coal miners, including gases from underground explosive blasting and aerosols of potentially contaminated water used for dust control.[8] Additional factors implicated in underground coal miners' accelerated lung function declines include weight gain, childhood pneumonia, and childhood environmental smoke exposures.[8]

Ventilatory Function

As CMDLD can manifest pathologically as disease of the lung parenchyma, small airways, and/or large airways, the corresponding physiologic defects appreciated on lung function testing may include obstructive, restrictive, or mixed defects.[56,99] The predominant functional abnormality in a given exposed miner will depend on the relative contribution of emphysema, airway disease, and fibrosis in the individual. Epidemiologic studies, as discussed earlier, have extensively documented the occurrence of exposure-related deficits in FEV_1 and forced vital capacity (FVC) in coal miners.[7,30–33,100,101] Although the magnitude of dust-related decline has varied between studies, an important subgroup of miners with accelerated decrements in lung function (FEV_1 decrease of >60 mL/year) has been identified. These miners were found to have more chest illnesses, more respiratory symptoms, and a greater risk of death from cardiovascular or nonmalignant respiratory disease than their cohorts with more stable lung function.[36] Airflow obstruction developing during coal mining has been associated with physiologic evidence of increased resistance to airflow in small (<2 mm internal diameter) airways, including abnormal airflow at low lung volumes and reduced density dependence of maximum expiratory flows.[54–56] Not surprisingly, deficits in lung function have also been documented in U.S. surface coal miners.[15]

Gas Exchange

Diffusing capacity has been studied in relation to radiographic changes of coal worker's pneumoconiosis.[101–103] The small, rounded opacities seen in miners with simple CWP have not generally been associated with measurable reductions in diffusion capacity, and large opacities of complicated CWP are not predictably associated with decreased diffusion. In contrast, miners with irregular opacities may have significant impairment in diffusion capacity, and abnormalities of gas exchange have been associated with increasing coal mine dust exposure independent of radiographic changes. Investigators have demonstrated a significant correlation between subjective measures of breathlessness and measurements of diffusion capacity, which may not be consistently observed with other pulmonary function parameters including FEV_1.[102] Gas exchange on exercise has also been investigated in coal miners.[48,49,104–106] Many reports have been based on patients referred for disability evaluations, and thus these reports suffer from ill-defined selection biases. Exposure–response relationships also are unclear with respect to findings in these series. Exertional hypoxia, pulmonary arterial hypertension, and excess ventilation have frequently been observed in miners, particularly those with complicated CWP or airflow obstruction.[1] However, the proportion of miners who show exertional gas exchange abnormalities in the absence of either PMF or clinically important airflow obstruction is still a topic of investigation.

■ Special Studies

BAL has been used in studying pathogenetic mechanisms in the pulmonary pathology in CWP. Rom et al.[107] reported BAL results for 15 symptomatic, nonsmoking coal miners with simple CWP. They found no significant difference between miners and controls in the number of cells recovered, the percentage distribution, and the release of superoxide anion or hydrogen peroxide. This contrasted with the findings in subjects with asbestosis and silicosis, whose values for spontaneous release of superoxide and hydrogen peroxide were significantly higher than controls. With regard to fibronectin and alveolar macrophage–derived growth factor, the miners with CWP had values that were elevated above controls and not different from the values obtained in subjects with asbestosis and silicosis.

Wallaert et al.[52] demonstrated significantly increased total number of lung cells recovered from 25 miners with simple and complicated CWP, as well as increased percentages of alveolar macrophages, lymphocytes, and neutrophils. Alveolar cells from miners with simple and complicated CWP spontaneously released significantly more superoxide, demonstrated by chemiluminescence, than controls.

■ Management of Coal Workers' Lung Diseases

There is no specific therapy for CMDLD. Whole lung lavage has been evaluated, but studies to date have not adequately defined the risks, benefits, and role in CMDLD management.[108] Thus, the crux of management is directed toward prevention, early recognition, and treatment of complications. The major clinical challenges are the recognition and management of airflow obstruction, respiratory infection, hypoxemia, respiratory failure, cor pulmonale, arrhythmias, and pneumothorax.

The recent epidemiologic findings of significantly increasing prevalence and rapid progression to severe disease in CMDLD should motivate workers to assure continuous control of dust, participate in medical surveillance programs, and exercise their rights to frequent dust measurements and job transfer when necessary. Previous surveillance programs have monitored worker lung health with chest radiographs every 5 years. The current health risks for coal workers necessitate not only chest imaging but also spirometry (every 1–3 years), to provide an opportunity to protect lung health through early detection of rapid functional declines. Identification of rapidly declining lung function or worsening radiographic disease should prompt strict dust controls and transfer to low-dust jobs when available. These workers should also be carefully advised about the risks of further dust exposures. Mine management and workers must assure that ventilation systems, water sprays, and other dust capture devices that are mandated by federal law are operating throughout the workshift and their effectiveness is continuously monitored.

Workers presenting with respiratory symptoms should have careful evaluation. Initial history and examination should be supplemented by a chest radiograph, spirometry with bronchodilators, diffusing capacity, electrocardiogram, and resting arterial blood–gas measurement as indicated. A comprehensive initial evaluation of the pulmonary system allows accurate assessment of the worker's respiratory health status and serves as a starting point for documenting the response to therapy or progression of disease. For miners who smoke, cessation is important regardless of symptoms, radiographic abnormalities, or functional status. Physician encouragement to stop smoking should be supplemented by support from smoking cessation groups, use of nicotine replacement, pharmacologic aids, and behavior modification techniques.[109]

Symptomatic reversible airflow obstruction may benefit from treatment with inhaled and oral bronchodilators. Patients with severe obstruction and inadequate improvement from the usual measures should be considered for a monitored trial of corticosteroids. If improvement is objectively documented, continuation of inhaled and, rarely, oral steroids may be of benefit. Hypoxemia can be a serious complication in advanced pneumoconiosis. It may be present at rest, with exercise, or during sleep. Chronic hypoxemia can lead to additional complications including polycythemia, pulmonary hypertension, cor pulmonale, and cerebral dysfunction. Therapy with low-flow oxygen is indicated when arterial oxygen tension is 55 torr or less. Oxygen therapy in this setting may improve exercise tolerance, reduce dyspnea, and prevent arrhythmias, polycythemia, and heart failure.[110] Patients with functional abnormalities and/or radiographic CWP should receive appropriate immunization with influenza and pneumococcal vaccines.[111] Bacterial and viral episodes of bronchitis or pneumonia should be promptly recognized and appropriately treated.

Patients with complicated pneumoconiosis, especially those who have been exposed to silica as well as coal mine dust, deserve special attention with regard to mycobacterial infection.[83] These patients are considered at higher risk of TB than the general U.S. population; thus a purified protein derivative test with >10 mm of induration is considered positive.[112] Patients with a history of weight loss, fever, sweats, or malaise should be promptly investigated with chest radiographs and sputum examination for acid-fast bacilli stains and cultures. Occasionally, the sputum may be negative and mycobacterial infection can only be documented by fiberoptic bronchoscopy with brushings and washings. Active tuberculosis in patients with CWP can, in general, be successfully treated with the usual drug regimens provided rifampin is one of the drugs used. However, some authorities would recommend that in coal miners with a significant history of concurrent silica exposure (such as motormen, roof bolters, drillers, and shaft development workers), the treatment regimens for tuberculosis should be more prolonged, and long-term follow-up is indicated in view of several reports of recurrent pulmonary tuberculosis in patients with PMF after completion of apparently adequate therapy.[113]

Respiratory failure may complicate advanced disease in coal miners, as it does in other chronic respiratory diseases. Ventilatory support measures are indicated when the failure is precipitated by a treatable complication. The application of ventilatory support measures should be clarified in advanced directives before the need arises.

Clinicians need to assess the contribution of occupational dust exposures to ventilatory impairments in their patients with a history of coal mine exposure. Factors that can assist in this include a careful work history with documentation of the mining region, duration, and categories of coal mine employment, as well as the duration and intensity of any tobacco smoking. Factors associated with an increased risk of a clinically important dust effect are a history of prolonged exposures in dusty jobs, exposures to higher rank coals, a younger age at first employment, and the finding of radiographic changes of CWP. Physicians should assist their patients with job-related impairments in obtaining appropriate compensation through state and national programs.[114]

Although there is no specific therapy for CMDLD, improved understanding of lung biology offers hope for interventions that address the mediators of this disease. Over the past decade, evidence has demonstrated the clinical benefits of antifibrotic treatment in moderate to severe idiopathic pulmonary fibrosis (IPF).[115] Pathways that may play a role in lung inflammation and fibrosis in IPF may overlap with those related to fibrosis in coal dust exposure. Nintedanib inhibits growth factor–stimulated migration and proliferation of fibroblasts and attenuates markers of TGF-β–induced transformation to myofibroblasts.[116] Pirfenidone inhibits TGF-β, collagen synthesis, and fibroblast proliferation, and mediates tissue repair.[117] Studies are underway that will elucidate the potential role of this agents in CMDLD. A trial is currently recruiting patients evaluating the safety and efficacy of Nintedanib in progressive fibrosing CMD-ILD, majority of which will constitute PMF patients (https://clinicaltrials.gov/ct2/show/NCT05067517). Similarly, there's an international effort evaluating the utility of antifibrotics in both coal and silica dust induced lung diseases (https://australianclinicaltrials.com/study/new-trial-into-treatment-of-silicosis-asbestosis-black-lung-or-coal-workers-pneumoconiosis-and-other-dust-diseases-the-nips-or-nintedanib-in-pneumoconiosis-trial/).

SILICOSIS

Silicosis is a fibrosing disease of the lungs caused by the inhalation, retention, and pulmonary reaction to crystalline silica.[118] Despite knowledge of the cause of this disorder (inhalation of dust containing respirable crystalline silica), this serious and potentially fatal occupational lung disease remains prevalent throughout the world.[119] Silica, or silicon dioxide, is the predominant component of the Earth's crust. Occupational exposure to silica particles of respirable size (aerodynamic diameter of 0.5–5.0 μm) has classically been associated with mining, quarrying, drilling, tunneling, and abrasive blasting with quartz-containing materials (sandblasting).[120–122] Many other occupations (Table 87-2) have potential for silica exposure and development of disease.[122] Because silica sand is inexpensive, accessible, and versatile, millions of workers throughout the world are at risk of disease. Occasionally, silicosis is reported from nonoccupational environmental exposures.[123] The disease is often unrecognized and underreported, and thus its true prevalence is substantially underestimated.[119] Fatal cases of silicosis and multiple cases from the same worksite continue to be recognized.[123,124]

■ Definition

Silicosis is an occupational lung disease attributable to the inhalation of silicon dioxide, commonly known as silica, in crystalline forms, usually as quartz, but also as other important crystalline forms of silica (i.e., cristobalite and tridymite).[125] These forms are also called "free silica" to distinguish them from the silicates. The silica content in different rock formations, such as sandstone, granite, and slate, varies from 20% to nearly 100%.

■ Workers in High-risk Occupations and Industries

Silicosis is considered the oldest occupational lung disease (alluded to by Hippocrates and Pliny), while new cases are still reported in

TABLE 87-2 Top 10 Industries and Occupations with Significantly Elevated Proportionate Mortality Ratios for Silicosis, 26 States, 1985–1999 (CDC/NIOSH National Occupational Respiratory Mortality System)

Industries	Occupations
Metal mining	Miscellaneous metal and plastic-processing machine operators
Miscellaneous nonmetallic mineral and stone products	Hand molders and shapers, except jewelers
Pottery and related products	Hand molding, casting, and forming occupations
Nonmetallic mining and quarrying, except fuel	Crushing and grinding machine operators
Iron and steel foundries	Molding and casting machine operators
Structural clay products	Mining engineers
Coal mining	Mining machine operators
Miscellaneous fabricated metal products	Mining occupations, not elsewhere classified
Miscellaneous retail stores	Supervisors, extractive occupations
Blast furnaces, steelworks, rolling, and finishing mills	Construction trades, not elsewhere classified

Data from Centers for Disease Control and Prevention: Silicosis mortality, prevention, and control—United States, 1968–2002. MMWR—Morbidity Mortality Weekly Report. 2005;54(16);401–405.

both the developed and developing world.[126–130] Workers' respiratory health is at risk whenever the Earth's crust is disturbed, or silica-containing rock or sand is used or processed. An estimated 2.3 million U.S. workers are potentially exposed to repairable crystalline silica.[131] Without adequate dust controls, silica exposures in many mechanized industrial processes can be a major cause of morbidity and mortality.[132] For instance, after introduction of pneumatic tools in the early 1900s, Vermont granite workers experienced "appallingly high mortality from silicosis and silicotuberculosis," which prompted the state government to enforce dust exposure limits in this industry.[133,134] The type of silica exposure appears to affect the risk of disease—processes such as drilling or sandblasting represent an increased risk of silicosis.[135,136] Even brief periods of exposure to high levels of freshly fractured silica can result in a lifetime of increased risk for disease.[137] Silicosis frequently develops or progresses after exposures have ceased.[138] In both developed and developing nations, workers in mining, quarrying, tunneling, abrasive blasting, construction, and foundry work continue to develop silicosis. Silicosis also continues to be diagnosed among workers from industries not previously recognized to offer a risk, reflecting the nearly ubiquitous presence of silica.[124,139] Example of newly identified work settings include artificial stone benchtop fabricators (also known as engineered, reconstituted, or manufactured stone and agglomerated quartz), denim jean sandblasters, jewelry polishers, and dental supplies. Workers in these modern industries are at risk for acute and accelerated silicosis over a short period of time due to high-intensity silica concentrations, oxidative stress from freshly fractured silica, and a rapid proinflammatory and profibrotic response.[140] In addition, artificial stone–associated silicosis poses significantly higher mortality risk than natural stone–associated silicosis.[141]

Forms of Silicosis: Exposure History and Clinicopathologic Descriptions

Chronic, accelerated, and acute forms of silicosis have been well characterized.[142] These clinical and pathologic expressions of the disease reflect differing exposure intensities, latency periods, and natural histories. The chronic or classic form usually follows 15 or more years of exposure to respirable dust-containing quartz.[143] Accelerated silicosis results from heavier exposures and develops more rapidly than the chronic form, often with a latency of 5 to 10 years.[144] It generally progresses inexorably even after exposure is interrupted. The acute form of silicosis is a consequence of exposures to high levels of respirable dust that contains silica.[145] The exposure period is usually from several months up to about 5 years, and the clinical course one of rapid progression.

Chronic (or classic) silicosis may be asymptomatic or result in insidiously progressive exertional dyspnea or cough (often mistakenly attributed to the aging process).[124,142] Radiographs show small (<10 mm) rounded opacities predominantly in the upper lung zones.[95] The pathologic hallmark in the lungs of patients with the chronic form is the silicotic nodule. The lesion is characterized by a cell-free central area of concentrically arranged, whorled, hyalinized collagen fibers, surrounded by cellular connective tissue with reticulin fibers (Fig. 87-4).[145] When examined under polarized light, the silicotic nodule shows birefringent particles, most prominent in the periphery.[146] Electron microscopy using specialized techniques can identify the specific mineral content of the particles but is rarely needed for routine diagnostic purposes.[147] Silicotic nodules in the visceral pleura, regional lymph nodes, and occasionally in other organs, may also result from exposure.[148] The small lung nodules of chronic silicosis may coalesce and result in larger shadows on the chest radiograph (>10 mm), heralding the onset of complicated or conglomerate silicosis (often referred to as PMF) (Fig. 87-5).[149] This progressive illness may begin after dust exposure has ceased.[150]

PMF is frequently associated with a clinically important compromise of lung structure and function—and as a consequence, symptoms of exertional dyspnea and reduced functional status.[151,152] Common laboratory findings include a diminished carbon monoxide diffusing capacity, reduced arterial oxygen tension at rest or with exercise, and classically a restrictive pattern on spirometry and lung volume measurement.[153,154] Concomitant dust-induced bronchitis or distortion of the bronchial tree may also result in productive cough, and multiple studies have now confirmed the presence of airflow obstruction in many patients with silica exposure with or without radiographic silicosis.[153–156] Recurrent bacterial infections may occur.[157] Weight loss and cavitation of the large opacities may herald tuberculosis or other mycobacterial infection.[124] Pneumothorax may be a life-threatening complication, since the lung may be difficult to reexpand.[158] Hypoxemic respiratory failure, cor pulmonale, and congestive heart failure are common late findings.

Accelerated silicosis results from exposures that are more intense and of shorter (5–10 years) duration than in the chronic form, while symptoms, radiographic findings, physiologic measurements, and lung pathology are similar.[159] Deterioration in lung function is more rapid, and mycobacterial infection more common. Findings consistent with autoimmune diseases, including scleroderma, rheumatoid arthritis, antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis, autoimmune hemolytic anemia, dermatopolymyositis, or systemic lupus, may be seen in association with silicosis, more often in the accelerated type.[160–163] The progression of radiographic abnormalities and functional impairment can be very rapid when autoimmune disease occurs with silicosis.[157]

Acute silicosis develops within a few months up to about 5 years after a massive inhalation of silica.[161] Dramatic dyspnea, weakness, and weight loss are often presenting symptoms.[159] Unlike chronic forms of silicosis, chest radiographs show diffuse alveolar filling,

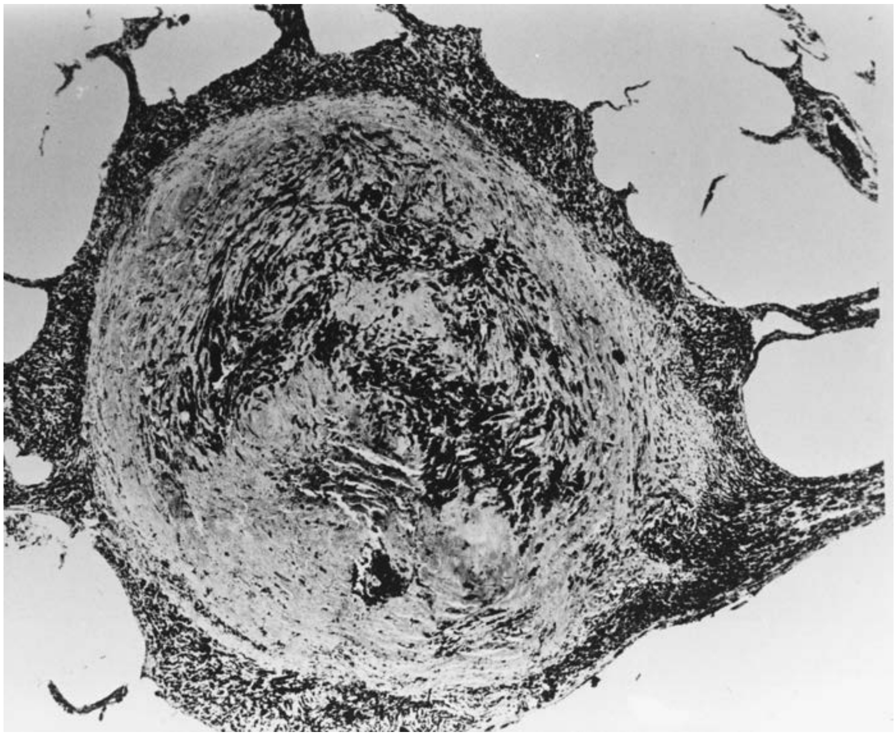

Figure 87-4 Lung pathology showing a classic silicotic nodule. (See text for description.) *(Reproduced with permission from Dr. Val Vallyathan, National Institute for Occupational Safety and Health, Morgantown, WV.)*

with a lower lung zone predominance.[164,165] Air bronchograms may be present. Histology resembles pulmonary alveolar proteinosis, with occasional extrapulmonary (renal and hepatic) abnormalities.[161,166–168] The usual clinical course is rapid progression to severe hypoxemic respiratory failure and death.

Tuberculosis may complicate silica exposure alone, and all forms of silicosis, but risk is greatest with acute and accelerated disease.[169,170] Both tuberculosis and nontuberculous (atypical) mycobacterial infections are seen.[143,171]

Even in the absence of radiographic silicosis, silica-exposed workers may also develop other diseases associated with occupational dust exposure, such as chronic bronchitis and associated emphysema. Progressive declines in lung function have been documented in workers from inhalation of silica and other occupational mineral dust exposures.[155]

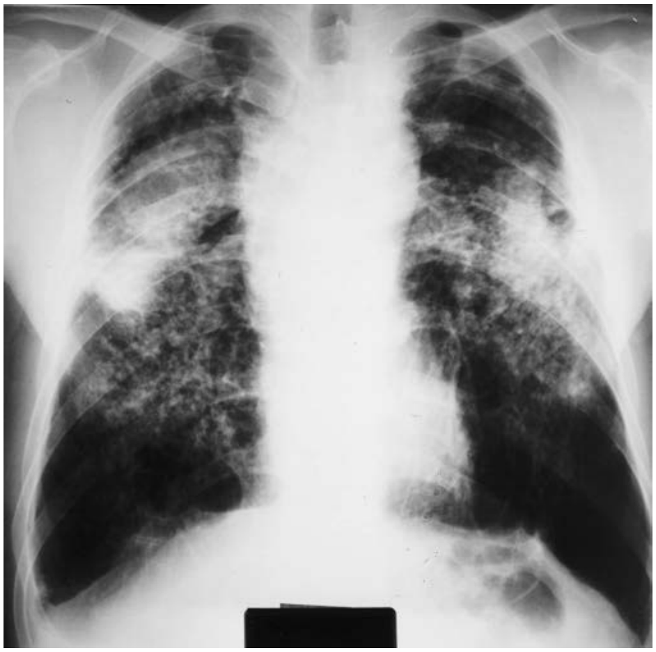

Figure 87-5 Radiographic changes of progressive massive fibrosis in a worker with complicated silicosis.

■ Pathogenesis and the Association with Tuberculosis

The precise mechanism of silica toxicity is uncertain, but it is thought to be mediated by generation of reactive oxygen species, both by the surface of silica particles themselves and by activation of alveolar macrophages.[136,172–174] Disease risk is related to the intensity and duration of the exposure; however, there is growing evidence that freshly fractured silica is more toxic than aged silica-containing dusts, perhaps related to reactive groups on the surface cleavage plane.[175] An abundance of evidence implicates the interaction between the pulmonary alveolar macrophage and silica particles deposited in the lung. Release of chemotactic factors (particularly the IL-1 signaling pathway) and inflammatory mediators, such as tumor necrosis factor, result in recruitment of polymorphonuclear leukocytes, lymphocytes, and additional macrophages.[118,125,176,177] The result of this cascade is chronic lung inflammation and eventually fibrosis. The central acellular zone of the silicotic nodule is surrounded by whorls of collagen and fibroblasts, and an active peripheral zone composed of macrophages, fibroblasts, plasma cells, and silica particles (Fig. 87-5).[161] Silica induces macrophage apoptosis, allowing the phagocytosed silica particle to be reintroduced into lung tissues and generate another cycle of phagocytosis and inflammation.[125,178] A large number of mediators have been implicated in the ongoing inflammation and fibrosis associated with silica exposure. These include IL-1B, TNF-α, TGF-β, fibronectin, and a family of inflammatory cytokines known as chemokines.[179–185] For instance, a study by Sellamuthu et al.[185] investigated mechanisms of crystalline silica–induced pulmonary toxicity by evaluating global gene expression in a human alveolar basal carcinoma epithelial cell line. Their results confirmed the involvement of previously identified molecular targets involved in silica toxicity, but also identified novel molecular pathways likely involved in toxicity. Upregulation of genes encoding for inflammatory cytokines/chemokines that function as chemoattractants and recruit inflammatory cells (especially PMNs) into the lungs appears to provide mechanisms for propagation and acceleration of initial silica-induced tissue damage. In addition, a recent meta-analysis has shown that a genetic polymorphism affecting TNF-α 308A/G and 238A/G is associated with increased susceptibility to silicosis in an Asian population.[186]

In acute silicosis, in contrast to the chronic forms, the alveolar space is filled with amorphous, lipoproteinaceous material that stains with periodic acid–Schiff (PAS) regent,[167,168] possibly related to abnormal handling and accumulation of pulmonary surfactant.[187–189]

As mentioned earlier among coal miners, DDF has been described in pathologic terms as a bridging fibrosis connecting various lesions of silicosis. This interstitial fibrosis appears to be a unique response in some silica-exposed individuals and is not thought to represent the concurrent development of UIP.

Immune system dysfunction is well described in association with silicosis, including increased prevalence of circulating immune complexes as well as increased production of serum autoantibodies, such as antinuclear antibody and RF.[190,191] The susceptibility of silicotic workers to infections, including tuberculosis and *Nocardia asteroides*, is likely related to the toxic effect of silica on pulmonary macrophages.[157,192] Thus, silica appears to activate humoral immunity (in a dysregulated manner), while impairing cell-mediated immunity.

Chen et al.[193] studied three cohorts of miners in different industries all with silica exposure. These researchers observed differences in the exposure-related risk of silicosis across the three cohorts. This epidemiologic finding lends support to the basic science literature suggesting that silica dust characteristics, in addition to cumulative respirable silica dust exposure, may affect the risk of silicosis.

Clinical Picture of Silicosis

When silicosis is symptomatic, the primary symptom is usually dyspnea, first noted with activity or exercise and later at rest. However, in the absence of other respiratory disease, shortness of breath may be absent, and the presentation may be an asymptomatic worker with an abnormal chest radiograph. The radiograph may at times show quite advanced disease with only minimal symptoms. The appearance or progression of dyspnea may herald the development of complications including tuberculosis, airway obstruction, PMF, or cor pulmonale. Productive cough is often present, secondary to chronic bronchitis from occupational dust exposure, tobacco use, or both. Cough may at times also be attributed to pressure on the trachea or mainstem bronchi from large masses of silicotic lymph nodes.

Other chest symptoms are less common. Hemoptysis is rare and should raise concern for complicating disorders, such as pulmonary neoplasms or mycobacterial infection. Wheeze and chest tightness may occur in silicosis but are usually associated with bronchitis or airflow obstruction. Chest pain and finger clubbing are not typically features of silicosis. Systemic symptoms, such as fever and weight loss, suggest complicating infection or neoplastic disease. Advanced forms of silicosis are associated with progressive respiratory failure with or without cor pulmonale. Few physical signs may be noted unless complications are present; inspiratory crackles are often absent.

Radiographic Patterns in Silicosis

The earliest radiographic signs of uncomplicated silicosis are generally small, rounded opacities. These can be categorized using the ILO International Classification of Radiographs of Pneumoconioses by size, shape, and profusion category.[21] In silicosis, rounded opacities of the "q" and "r" type dominate (Table 87-1). Other patterns also have been described, including linear or irregular shadows. The opacities seen on the radiograph represent the summation of pathologic silicotic nodules and associated changes. They are usually found to predominate initially in the upper lung zones and may progress to involve other zones.[95] Hilar lymphadenopathy is also noted, sometimes before nodular parenchymal shadows.[95] Eggshell calcification of the lymph nodes is strongly suggestive of silicosis in the appropriate clinical context, although this feature is uncommon.[194] The development of PMF is indicated by large radiographic opacities, which are categorized by size as A, B, or C (Table 87-1), using the ILO classification.[21] PMF lesions tend to contract to the upper lung zones, leaving areas of compensatory emphysema at their margins and in the lung bases.[95] The contraction process causes small pneumoconiotic opacities that previously were evident on the radiograph to become less visible or at times disappear. Pleural abnormalities are occasionally observed on routine chest radiographs with silicosis; however, CT scanning often documents localized pleural thickening, particularly in association with conglomerate lesions.[195] Pleural effusions are less frequently noted. The radiographic distinction between large pneumoconiotic lesions and lung malignancies may be difficult, particularly if no earlier radiographs are available. As in complicated CWP, FDG-PET scanning may sometimes be helpful in this distinction, but false positives occur.[196–198] Cavitation or a rapid change in the radiographic appearance of a large silicotic lesion may be due to ischemic necrosis but should always prompt a vigorous search for mycobacterial disease. Acute silicosis may present with an alveolar filling pattern and rapid development of complicated mass lesions.[164]

Lung Functional Abnormalities in Silicosis

Pulmonary function tests, including spirometry and diffusing capacity, are helpful in the clinical evaluation of individuals with suspected silicosis. Spirometry may also be of value in early recognition of the health effects from occupational dust exposures, as it may detect physiologic abnormalities that may precede radiographic changes.[199] No specific or characteristic pattern of ventilatory impairment is present in silicosis. Spirometry may be normal, or when abnormal, the tracings may show obstruction, restriction, or a mixed pattern.[199] Numerous studies have investigated the impact of silica dust exposure and lung function.[200–202] These data suggest that obstruction may indeed be the more common finding. Silica and mixed dust exposures may lead to clinically important airflow limitation independent of radiographic abnormality; however there is some evidence that lung function deficits are more associated with silica-related emphysema than nodularity on imaging.[151] Functional changes tend to be more marked with advanced radiologic categories.[151] However, no good correlation exists between radiographic abnormalities and ventilatory impairment, and workers experience lung function loss proportionate to the duration and intensity of silica dust exposure.[153] Diffusing impairment may also occur in the absence of ventilatory impairment. In acute and accelerated silicosis, functional changes generally occur earlier, are more marked, and progress more rapidly.[165,203–205] Reduced six-minute walk distance (6MWD) was noted to be a prognostic factor for both hospitalization and mortality in silicosis patients suggestive of its utility for monitoring of their health.[206] In acute silicosis, radiographic progression is accompanied by increasing ventilatory impairment and gas exchange abnormalities, which leads to respiratory failure and eventually to death from intractable hypoxemia.[157]

Complications and Special Diagnostic Issues in Silicosis

With a history of sufficient exposure and a characteristic radiograph, the diagnosis of silicosis is generally not difficult to establish. Challenges arise when the radiologic features are unusual or the history of exposure is not recognized. Lung biopsy is rarely required to establish the diagnosis. However, tissue samples may be helpful in some clinical settings when complications are present or the differential diagnosis includes tuberculosis, neoplasm, or PMF. Biopsy material should be sent for culture, and in research settings, dust analysis may be a useful additional measure. When tissue is required, open or thoracoscopic lung biopsies are generally necessary for adequate material for examination, to assure satisfactory hemostasis, and due to concern about life-threatening pneumothorax in the fibrotic lung. Some evidence suggests BAL and transbronchial biopsy may be of diagnostic aid in some cases where the diagnosis of silicosis is not straightforward.[207] Endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA) can be a useful diagnostic tool in suspected silicosis patients with mediastinal lymphadenopathy.[208]

Vigilance for infectious complications, especially tuberculosis and other mycobacteria, cannot be overemphasized. Any fever, weight loss, worsening symptoms, or radiographic changes should trigger a workup to exclude this treatable problem. In acute silicosis, *Nocardia* and fungal infections must be considered.[157]

In 1997, the International Agency for Research on Cancer (IARC) reclassified crystalline silica as a group I carcinogen. This new designation indicates IARC found "sufficient data" to determine that crystalline silica in the form of quartz or cristobalite dust is carcinogenic to humans.[209] Uncertainty remains over the pathogenic mechanisms for the development of lung cancer in silica-exposed populations, and the relationship between silicosis (or lung fibrosis) and cancer continues to be studied. IARC noted that a link to carcinogenicity was not detected in every type of industrial exposure and may be related to an interaction between the silica dust and other environmental factors.[209,210] Regardless of the mechanism, there is ample evidence confirming a causal link between occupational exposure to silica and lung cancer.

A relationship between renal complications and silica exposure has been suspected since the early 20th century.[211] A 2002 study reported a 5.1% excess risk of end-stage renal disease (ESRD) and a 1.8% excess risk of death from kidney disease in individuals exposed to silica.[211] Glomerulonephritis and nephrotic syndrome have been described in association with silica exposure.[160,212–214] The specific mechanisms of renal injury are not completely understood, but evidence suggests injury may occur by both direct (silica particulate in the kidney) and indirect insults (immunologic injury by immune complex formation).[160,214]

Several autoimmune diseases are clearly linked with silica dust exposure.[215] Perhaps the most well-known of these is scleroderma, first reported in the 1910s and subsequently described by Erasmus (sometimes referred to as Erasmus syndrome) in 1957 from investigations into South African gold miners.[216,217] A study analyzing the prevalence of connective tissue disease in silicosis between 1985 to 2006 reported a 24-fold risk of developing scleroderma among silicotics compared to the general population.[160] This study also found two- to eightfold risks for rheumatoid arthritis and systemic lupus erythematosus, as well as a striking increased prevalence of ANCA-associated vasculitis. A Finnish study also suggested a strong association between silica exposure and rheumatoid arthritis.[218] An earlier NIOSH review of the health implications of silica exposure cited the most commonly associated autoimmune diseases to be scleroderma, systemic lupus erythematosus (lupus), rheumatoid arthritis, autoimmune hemolytic anemia, and dermatomyositis or dermatopolymyositis.[159] An animal model has suggested a multi-hit model of autoimmunity where exposures to silica and virus exposure act synergistically to induce autoimmunity.[219]

Prevention of Silicosis

Prevention remains the principal goal in dealing with this occupational lung disease. Despite the current OSHA PEL for respirable crystalline silica of 100 μg/m^3 as an 8-h time-weighted average, silica-exposed workers continue to develop disease.[220,221] NIOSH since 1974 has recommended the PEL be reduced to 50 μg/m^3 as a time-weighted average for up to 10 h/day.[220] Workers with longer exposure at a lower concentration were noted to be at higher risk for silicosis than those with the same cumulative exposure for a shorter period of time at higher concentrations. In addition, the rate of disease progression was related to subsequent concentration of silica dust exposed to the workers.[222] Effective exposure controls are available for most processes and include process enclosure, wet abrasive techniques, and local exhaust ventilation, combined with a comprehensive approach to personal protection. Where possible, less hazardous agents should be substituted for silica. Unfortunately, noncompliance with the current permissive exposure limit appears common in many work environments.[223,224] Both employers and workers must remain vigilant regarding the hazards of silica dust exposure and control measures.

If silicosis is recognized in a worker, termination of any continuing exposures is advisable. Unfortunately, the disease often will progress even without further silica exposure. The finding of a case of silicosis is a "sentinel health event" and should prompt a thorough evaluation of workplace exposures and control measures by a competent authority, with the goal of recognizing the sources of the hazard and protecting other workers who may continue to be at risk.

Medical Screening and Surveillance in Silicosis

Workers exposed to silica and other mineral dusts should be monitored on a regular basis for adverse health effects as a supplement to, but not a substitute for, exposure monitoring and control. Health screening commonly includes periodic evaluation of respiratory symptoms, spirometric abnormalities, and radiographic changes. There is evidence that, if silicosis subsequently develops, workers who have participated in periodic health monitoring experience reduced severity of disease.[225] Evaluation for tuberculosis infection also should be performed. Historically, this was done using intradermal skin testing, although new diagnostic techniques useful in the screening and diagnosis of TB termed interferon gamma release assays (IGRAs) have come to market. While not specifically studied in the silica-exposed population, studies in general populations suggest equal if not greater specificity and sensitivity in comparison with standard dermal screening for TB. The advantages offered by these tests are as follows: (1) there is no interference with the BCG vaccine, (2) subjective interpretation is avoided, (3) a second appointment for reading the results is avoided, and (4) the test incorporates a positive control that provides valuable information for interpreting an apparently negative test as either a true negative or indeterminate as a result of technical errors or immunosuppression.[226] In addition to reporting of health surveillance results to the individual workers, health data from all workers at a plant or operation should be periodically analyzed (e.g., every 1–3 years) to assess the adequacy of prevention activities.

Several biomarkers have been investigated to aid early identification of silicosis, including higher levels of serum nephronectin (extracellular matrix–related ligand) and high-mobility group box 1 (HMGB-1).[227,228] However, their application remains limited to research settings and is largely investigational.

Therapy, Management of Complications, and Control of Silicosis

When prevention has been unsuccessful and silicosis has developed, therapy is directed largely at detecting and treating complications. Therapeutic measures are similar to those commonly used in the management of airflow obstruction, infection, pneumothorax, hypoxemia, and respiratory failure complicating other pulmonary disease. Historically, there have been a number of unsuccessful attempts to find a drug treatment that can reverse silicosis.[229,230] Whole lung lavage has been attempted with the hope of removing dust, inflammatory cells, and other mediators to potentially ameliorate disease progression.[108] Currently, there are no data to confirm that this or any other therapy alters the natural progression of human silicosis. Because of the high prevalence of disease in some countries, investigations of combinations of drugs and other interventions continue.

For workers with a diagnosis of silicosis, further exposure to silica-containing dusts is undesirable. If the disease is advanced or has occurred after a relatively short exposure (i.e., <15 years), then further dust exposure should be assiduously avoided. Advice on job reassignment should be considered in the context of the worker's age, symptoms, functional status, and the current working conditions and measured silica exposures. Patients with silicosis may have few symptoms or findings early in the disease; however, physicians should be aware that many states have a strict time limit, dating from the physician's recognition of findings of silicosis, regarding application for workers' compensation and reimbursement of medical costs.

In the medical management of silicosis, vigilance for complicating infection, especially tuberculosis, is critical. The use of bacillus Calmette-Guérin (BCG) vaccine in the tuberculin-negative silicotic patient is not recommended, but the use of preventive isoniazid (INH) therapy in the tuberculin-positive silicotic patient is advised.[231] The diagnosis of active tuberculosis infection in patients with silicosis can be difficult. Clinical symptoms of weight loss, fever, sweats, and malaise should prompt radiographic evaluation and sputum acid-fast bacilli stains and cultures.[232] Radiographic changes with infection may be subtle and atypical. Enlargement or cavitation in conglomerate lesions or nodular opacities is of particular concern. Bacteriologic studies on expectorated sputum are indicated but may not be reliable in silicotuberculosis because expectoration may produce only scant numbers of active organisms. Fiberoptic bronchoscopy for additional specimens for culture and study may be helpful in establishing a diagnosis of active disease. The use of multidrug therapy for suspected active disease is justified at a lower level of suspicion in silicotics compared to the nonsilicotic patient, due to the difficulty in firmly establishing evidence for active infection. To obtain satisfactory results in the presence of silicosis, antituberculous treatment must be more prolonged, with regimens lasting at least 8 months.[113] A multiplicative increase in risk of mycobacterial infection is associated with the combination of silicosis and human immunodeficiency virus (HIV) infection, as has been encountered in South African gold miners.[233] Coinfection with HIV and tuberculosis may also have an adverse impact on progression of silicosis and lung function decline.[234] These infections represent major clinical and public health challenges.[235] Prolonged treatment is essential, and there is potential for both adverse drug reactions and interactions between antiretroviral and antituberculous therapy. Recommended approaches continue to evolve, and clinicians should consult the latest authoritative recommendations.

Ventilatory support for respiratory failure may be indicated when precipitated by a treatable complication. Pneumothorax, spontaneous and ventilator related, is usually treated by chest tube insertion. Bronchopleural fistula may develop, and surgical consultation and management should be considered.

Acute silicosis may rapidly progress to respiratory failure. When this disease resembles pulmonary alveolar proteinosis and severe hypoxemia is present, aggressive therapy has included massive whole lung lavage with the patient under general anesthesia in an attempt to improve gas exchange and remove alveolar debris. Although appealing in concept, the efficacy of whole lung lavage has not been established.[236] Glucocorticoid therapy also has been used for acute silicosis; however, it also is of unproven benefit.[237,238]

Some younger patients with end-stage silicosis may be considered candidates for lung or heart–lung transplantation by centers experienced with this expensive and high-risk procedure.[239] Early referral and evaluation for this intervention may be offered to selected patients.

The discussion of an aggressive and high-technology therapeutic intervention such as transplantation serves to dramatically underscore the serious and potentially fatal nature of silicosis, as well as to emphasize the crucial role for primary prevention. The control of silicosis ultimately depends upon the control of workplace dust exposures. This is accomplished by rigorous and conscientious application of fundamental occupational hygiene and engineering principles, with a commitment to the preservation of worker health.

PREVENTION STRATEGIES FOR COAL WORKERS' LUNG DISEASES AND SILICOSIS

The control of coal workers' lung diseases and silicosis in both the developed and developing world requires comprehensive prevention strategies, including exposure control, medical surveillance, research, and education. Example approaches include the following:

- Major efforts must be directed to installation of effective engineering controls and improvements in work practices to progressively reduce dust exposures to recommended levels. These efforts are labeled primary prevention. In selected situations, personal respiratory protection also can play a role, particularly during short-term operations or unusual/emergency conditions, and while engineering controls are being modified or improved. The use of respirators will only be effective when part of a professionally managed comprehensive respiratory protection program and should never be relied upon outside of such a program.
- Primary prevention should involve ongoing dust exposure monitoring and include mechanisms for feedback to modify and improve working conditions if exposures are measured above recommended levels. Even exposure at currently permissible levels has been recognized to represent a risk of disease.
- Secondary prevention through medical screening and surveillance should be designed to benefit the individual worker and other potentially exposed workers. Illness identified through medical screening represents a failure of primary prevention, and thus should trigger feedback to those responsible for environmental monitoring, exposure controls, and work practice evaluations.
- Education about the respiratory health hazards from uncontrolled exposures to silica and coal mine dust must be available to workers, employers, managers, and healthcare providers.
- Information on the cumulative burden of disease should be monitored over time for both silica and coal mine dust.
- Research into mining-related lung diseases should be encouraged to improve recognition, monitoring, exposure reduction, and therapy, and to increase understanding of pathogenesis. Research efforts should supplement, not displace, attention to dust control.
- Clinicians who recognize coal-related diseases or silicosis in their patients should attempt to determine whether ongoing workplace exposures present a continuing risk to current workers, while maintaining the confidentiality of the patient–physician relationship. Assistance in this can often be obtained through local or state health departments, occupational medicine groups, and federal agencies. Reporting of occupational diseases is required in many states.

CONCLUSIONS

Although much is known about the causes, pathogenesis, natural history, and prevention of dust-related respiratory diseases, the pneumoconioses remain important causes of morbidity and mortality in the United States and throughout the world. Healthcare providers need to maintain medical vigilance and familiarity with the clinical features and management of these disorders, especially those whose clinical practice includes persons with significant mining or industrial employment. When patients are exposed to occupational lung hazards, they should be provided effective workplace protections, respiratory health monitoring, timely and accurate recognition and management of dust diseases and their complications, and referrals for public health evaluations and equitable compensation whenever appropriate.

CHAPTER 88

Occupational Asthma, Byssinosis, and Industrial Bronchitis

Shu-Yi Liao
David C. Christiani

INTRODUCTION

Workplace inhalational hazards such as dust, fumes, and organic substances can cause various nonmalignant respiratory diseases. These occupational exposures may cause airway diseases and parenchymal diseases. Occupation-related lung parenchymal diseases, such as hypersensitivity pneumonitis, obliterative bronchiolitis, and chronic beryllium disease are considered elsewhere. In this chapter, we discuss occupational asthma, byssinosis, and industrial bronchitis.

OCCUPATIONAL ASTHMA

Below we describe important aspects of occupational asthma, including its epidemiology, causative agents, risk factors, pathogenetic mechanisms, clinical presentations, diagnosis, and management.

■ Epidemiology

Work-related asthma is the most common *occupational lung disease*. There are two categories: (1) occupational, or work-related, asthma that is caused de novo by work, and (2) work-exacerbated asthma, which implies a work-related worsening in the setting of preexisting asthma.[1] The prevalence of work-related asthma is difficult to determine. An international estimate attributes 15% to 20% of adult-onset asthma to workplace exposure.[2] A recent systemic review indicated the overall occupational population attributable fraction was 16%, with wide 95% confidence intervals between 3.8 and 27.1%.[3] The incidence of occupational asthma is 3% to 36% and varies among different industries, based on international studies in workers with different occupations[4] (Table 88-1).

TABLE 88-1 Incidence of Occupational Asthma in Main Occupations

Occupation/Exposed Antigen	Number of Cases	Incidence (%)	Country
Snow crab processors	303	15.6	Canada
Guar gum (natural polysaccharide)	151	3.0	Canada
Painters (isocyanate)	730	7.1 (all subjects were non-smokers)	Italy
Poultry workers	134	11.0	South Africa
Rat allergens	113	4.4	France
Natural rubber latex (health care workers in general hospital)	196	7.1	Italy
Florists	128	14.1	USA
Supermarket bakery workers	66	9.0	UK
Strawberry growing industry workers	43	4.7	Japan
Oyster shucker (sea squirt)	250–417	18.0–36.0	Japan

Data from Mapp CE, Boschetto P, Maestrelli P, et al. Occupational asthma. Am J Respir Crit Care Med. 2005;172(3):280–305.

■ Agents That Cause Occupational Asthma

Many agents cause occupational asthma. Two categories of agents can be classified based on molecular weight and differing mechanisms causing disease: high-molecular-weight (HMW) compounds (>5 to 10 kDa), and low-molecular-weight (LMW) compounds. A list of causative compounds and occupations at risk is provided in Table 88-2. The website *www.occupationalasthma.com* also provides up-to-date information on agents known to cause occupational asthma.

■ Risk Factors

Risk factors include exposure to a respiratory sensitizer, high intensity of exposure, genetic predisposition, smoking status, and preexisting atopy.

It has been shown that the major histocompatibility complex class II proteins are important for occupational asthma susceptibility if the occupational exposure is due to acid anhydrides, diisocyanates, western red cedar, platinum salts, latex, and/or animal proteins.

Genotypes of glutathione S-transferase[5] and N-acetyltransferase[6,7] also are associated with development of occupational asthma. A large gene–environmental study consisting of 2599 European participants showed a gene–environmental interaction between the exposure to LMW agents/irritants and genes associated with oxidative stress, such as *PLA2G4A*, *PLA2R1*, *PRKCA*, *PRKD1*, and *RELA*.[8] Susceptible genotypes may differ based on the occupational exposure types (HMW vs. LMW) and are shown in Table 88-3.[9]

Smoking is a risk factor for sensitization to HMW compound–related occupational exposures, such as coffee, castor beans, snow crab, or shrimp, and some LMW-related occupational exposures, such as platinum salts and phthalic anhydride.[10] In these instances, smoking may interact with atopy, another risk factor for occupational asthma, to increase the risk of antigen sensitization in atopic smokers.[11,12] However, sensitization to an agent is not equivalent to the development of occupational asthma, and further epidemiologic studies are needed to verify a causal relationship between smoking, atopy, and susceptibility to occupational asthma.

Atopy is also associated with sensitization, especially to the HMW compounds that induce an immediate antibody response, such as production of IgE.[13,14] While atopy can increase the risk of sensitization, the positive predictive value of atopy per se for development of asthma symptoms is low.[15,16]

■ Mechanism and Pathogenesis

The mechanism and pathogenesis of developing occupational asthma can be divided into immunologic and nonimmunologic (irritant) processes. However, some agents, such as diisocyanates, can induce asthma through both mechanisms.

Immunologic Mechanisms

Immunologic occupational asthma is characterized by a latent period; in general, a small quantity of the insult can induce severe

TABLE 88-2 Causes of Occupational Asthma

Categories	Occupations at Risk	Major Putative Component
High-molecular-weight compounds		
Animal products	Animal handlers Veterinarians	Pelt or urinary proteins
Seafoods	Crab or prawn processors Oyster farmers	Water-extractable proteins
Insects	Entomologists Grain workers Laboratory workers River workers Flight crews	Insect proteins
Plants	Grain handlers Bakers Tea workers Brewery chemists Tobacco manufacturers	Extractable plant proteins
Biologic enzymes	Detergent industry workers Bakers Pharmaceutical workers	*Bacillus subtilis*, trypsin, pancreatin, papain, pepsin
Latex	Health care workers Doll manufacturers Glove makers	Latex rubber extract
Gums	Printers Gum manufacturers	Gum acacia Gum tragacanth
Low-molecular-weight compounds		
Diisocyanates	Polyurethane workers Plastic workers Foundry workers Spray painters	Isocyanate-protein complex
Anhydrides	Epoxy resin workers Plastics workers	Phthalic anhydride–protein complexes
Wood dust	Carpenters Sawmill workers	Plicatic acid (western red cedar) Wood dust extracts
Fluxes	Aluminum solderers Electronics workers	Aminoethylethanolamine
Pharmaceuticals	Pharmaceutical manufacturers	Antibiotics, psyllium, piperazine
Fixatives	Hospital workers	Formaldehyde, glutaraldehyde
Diesel exhaust	Farmers, diesel mechanics	Nitrogen oxides, sulfur dioxide, particulates

symptoms. This immunologic mechanism may be IgE-mediated or non-IgE-mediated. For occupational asthma, most of the immunologic reactions are IgE-mediated. HMW compounds (e.g., animal protein, flour, and latex) usually cause occupational asthma via IgE-mediated processes. This accounts for the observations that serum IgE antibodies to the specific agent can sometimes be identified and skin tests may be positive using the offending substance extracts. Consequently, atopic individuals are at a higher risk of developing occupational asthma from exposure to HMW agents.

LMW compounds, on other hand, tend to cause occupational asthma though non-IgE-mediated immunologic reactions. Notable exceptions are platinum salts and some acid anhydrides that can induce specific IgE antibodies. The mechanisms of non-IgE-mediated immunologic process with exposure to LMW agents remain unclear, although there is some evidence that the pathogenesis of red cedar, cobalt, nickel salts, or isocyanate-related asthma may involve T cell–mediated responses.[17,18]

Nonimmunologic Mechanisms

Occupational asthma caused by nonimmunologic mechanisms has no latency period. Several mechanisms are at play. Accidental exposure to high doses of ammonia, smoke, or chlorine may cause acute airway injury (irritant-induced reactive airways dysfunction) through the mechanism of loss of epithelial-derived relaxing factors, leading to neurogenic inflammation and cytokine release from mast cells.[19] Other agents, such as organophosphates,[20] may cause bronchoconstriction through anticholinergic effects, and diisocyanates[21] by blocking β2-adrenergic receptors.

■ Clinical Presentations

Occupational asthma may be more severe than non-work-related asthma and may result in higher medication use, worse asthma control, and more rapid lung function decline.[22] Clinical symptoms of occupational asthma overlap with non-work-related asthma. Common symptoms include wheezing, shortness of breath, and cough. Physicians should suspect potential occupational causes, especially in patients with adult-onset asthma.

Two main types of occupational asthma with different time frames for symptom onset after exposure should be considered: (1) occupational asthma with a latency of weeks or months after the exposure (generally immunologically mediated) and (2) occupational asthma without latency (i.e., irritant asthma), which is usually not immunologically mediated.[20]

Occupational Asthma with Latency

Patients with this type of occupational asthma develop symptoms weeks or months after the exposure as a result of sensitization. The offending agents include HMW and LMW compounds. Since this is an anamnestic response, the amount of the offending agent can be low and still cause severe bronchoconstriction. Symptoms may differ depending on the offending agents. HMW agents usually cause more conjunctivitis and rhinitis compared with LMW agents.[23]

Occupational Asthma Without Latency (Irritant Asthma)

Symptoms in irritant asthma develop within hours of exposure (<24 h). The exposure level usually is a high concentration. Patients may encounter symptoms similar to those of traditional asthma attacks, such as acute shortness of breath and wheezing. Symptoms typically persist for a couple of months, although some patients develop chronic asthma.[24]

■ Diagnosis

Three key components should be considered when thinking about the diagnosis of work-related asthma: (1) workers with de novo asthma or exacerbation of previously quiescent asthma, (2) exposure to a sensitizer or irritant that is known to cause occupational asthma, and (3) a causal relationship between agents and the worker's symptoms.

To facilitate diagnosis, the National Institute for Occupational Safety and Health (NIOSH) has created a worksheet: Decision

TABLE 88-3 Susceptible Genotypes of Occupational Asthma Based on Occupational Exposure Types

Genetic Marker	Occupational Exposure	Molecular Weight	Population
HLA-DQB1	TDI/red cedar sawmill	Low	Caucasian
HLA-DRB1-DQB1-DPB1	TDI	Low	Korean
CTNN3	TDI	Low	Korean, Caucasian
GSTP1	TDI/DI	Low	Caucasian
GSTM1	TDI/DI	Low	Caucasian
SOD2	DI	Low	Caucasian

Logic for Work-Related Asthma Surveillance Case Identification and Classification (*www.cdc.gov/niosh/topics/surveillance*). The first step in the process is establishing a diagnosis of asthma and an association between the symptoms and work. If the patient has asthma, and symptoms are related to the work, a diagnosis of work-related asthma is made. The next step is differentiating work-exacerbated asthma from new-onset, work-related asthma. If the patient has no recent history of asthma (i.e., is asymptomatic and not on asthma treatment for 2 years prior to entering the new occupational setting), a diagnosis of new-onset work-related asthma can be made. Differentiation between occupational asthma without latency and occupational asthma with latency is based on the time between the exposure and onset of symptoms. As noted previously, irritant asthma develops within 24 h after a one-time, high-level inhalation exposure to an irritant gas, fume, smoke, or vapor, and symptoms persist for at least 3 months.

In addition to the history, several diagnostic tests may provide objective evidence for the diagnosis of occupational asthma. These include (1) work-related changes in serially measured forced expiratory volume in 1 s (FEV$_1$) or peak expiratory flow rate (PEFR); (2) work-related changes in bronchial responsiveness, as measured by serial, nonspecific inhalation challenge tests; and (3) a positive response to a specific inhalation challenge test with an agent to which the patient has been exposed at work. Details of diagnostic tests are given below.

Diagnostic Tests

Three main diagnostic tests may offer objective evidence for the diagnosis of occupational asthma: (1) pulmonary function tests, (2) bronchial provocation tests, and (3) immunologic tests. The overall sensitivity, specificity, pros, and cons of each are shown in Table 88-4. In addition, recent studies have discovered several biomarkers for occupational asthma that are discussed below.

Pulmonary Function Tests FEV$_1$ or PEFR are the two most commonly used measurements for the diagnosis of occupational asthma. Workers may present with normal spirometry while not in the workplace. Therefore, the timing of this pulmonary function test is important, and pre- and post-work measurements are needed.

Peak flow monitors are easy to use on the job. Four measurements each day are usually recommended: (1) upon awakening, (2) at the beginning of the workday, (3) at the end of the workday, and (4) prior to bed. The measurements should be performed daily for at least 4 weeks. Some experts have proposed more intense and frequent measurements with a 2-h interval, but this approach may not be practical with a busy work schedule.[26] The limitation of the PEFR measurement is that it is effort-dependent; however, it can still be used as a screening tool. If suspicion of occupational asthma remains high after the PEFR measurement, confirmatory measurements of FEV$_1$ and FVC by a trained technician in the workplace may be needed.

Bronchial Provocation Tests A nonspecific bronchial provocation test is useful to establish an initial diagnosis of asthma, although it cannot differentiate occupational asthma versus general asthma. The most commonly utilized agent in the United States is methacholine, but histamine also can be used. A positive test is defined as a provocative concentration producing a 20% decline in FEV$_1$ (PC$_{20}$) of less than 8 mg/mL of methacholine (8–16 mg/mL considered

TABLE 88-4 Diagnostic Tests for Occupational Asthma

Test	Sensitivity	Specificity	Comment
Immunologic testing	Good	Intermediate	HMW and some LMW compounds (IgE response needed)
Spirometry before and after work	Intermediate	Poor	Objective and simple
PEFR monitoring	Intermediate	Poor	Patient cooperation needed, inexpensive
MCh Challenge	Good	Poor	Test for asthma, not OA
Specific inhalation challenge	Good	Good	Gold standard, expensive and can be dangerous

borderline).[27] The test is safe, and there are performance guidelines elaborated by the American Thoracic Society and European Respiratory Society.[27,28]

A specific inhalation challenge test can be performed for the diagnosis of occupational asthma and determining whether a patient's symptoms are due to a particular agent. However, risks associated with the test include prolonged bronchospasm requiring clinical intervention. The test needs to be closely monitored and performed under a physician's supervision, usually in a hospital-based setting. The test is generally considered the gold standard for the diagnosis of occupational asthma, but it is rarely performed in the United States[29] due to the cost and high risks.

Immunologic Tests Immunologic tests can be used in immunologically mediated occupational asthma (mostly due to HMW compounds). A skin prick test using a panel of allergens can be useful in determining sensitization. Immunologic tests using an extract of the suspected specific offending agent can be useful in establishing the diagnosis. According to a systemic review of studies using specific inhalation challenge as the gold standard, sensitivity and specificity for the skin prick test are 80.6% and 59.6%, respectively.[25] Several extracts, such as flour, coffee, and animal protein, have been used for skin testing.[17]

Serum-specific IgE antibodies are another test used to facilitate the diagnosis of occupational asthma (using specific inhalation challenge as the gold standard); overall sensitivity and specificity are 73.3% and 79.0%, respectively.[25] However, immunologic tests only indicate sensitization and need to be considered in conjunction with the history and other diagnostic tests to make a definitive diagnosis of occupational asthma. Moreover, extracts are not available for the majority of chemicals implicated in causing asthma (Table 88-2).

Other Diagnostic Biomarkers In the past several decades, studies have addressed identification of biomarkers in occupational asthma. In a review by Brooks,[30] the percentage of eosinophils in induced sputum is noted to increase after specific inhalation challenge in patients with occupational asthma. Exhaled nitric oxide may also be compared before and after work as an aid in diagnosis, although confounders, such as infection and smoking, may complicate interpretation of findings, making use of this test controversial in the diagnosis of occupational asthma. Finally, elevated systemic biomarkers, such as interleukin 6 and tumor necrosis factor α in serum, nasal lavage fluid, or bronchoalveolar lavage, also may offer evidence of occupational asthma;[30] however, the findings are nonspecific.

■ Management

Removing workers with occupational asthma from offending environments is the first and an essential step. In some scenarios, an exposure reduction in the workplace may allow workers to continue working without progressive respiratory symptoms. If changing jobs is unrealistic or not feasible, and the offending agent or process cannot be eliminated, the use of personal protective equipment may reduce attacks, although it is rarely sufficient to protect sensitized workers. HMW compounds generally can be avoided through use of a high-efficiency particulate air mask, while helmet respirators with an isolated air source may be needed in workers who work with LMW compounds. Continued exposure, even with PPE, is associated with worse outcomes.

Notably, avoiding exposure is not enough. A study of refinery workers exposed to platinum salts showed that 77% of workers continued to suffer from asthma, and 86% had airway obstruction or bronchial hyperresponsiveness despite job relocation and passage of several years (median, 67 months) after the initial diagnosis.[31] Currently, there is no specific treatment for occupational asthma; however, treatment of general asthma is warranted if the patient has persistent asthma symptoms despite removal from the exposure.

BYSSINOSIS

Over 60 million people worldwide work in the textile and clothing industry.[32] In some workers, respiratory symptoms developed after exposure to cotton, flax, or hemp dust. These adverse respiratory effects were first described more than 100 years ago as a syndrome now known as *byssinosis*. Over the past years, byssinosis has been referred to as cotton worker's lung, brown lung disease, and Monday morning fever (as workers commonly have a fever and respiratory symptoms after not having worked over the weekend).

■ Epidemiology

The Centers for Disease Control and Prevention (CDC) published mortality data for byssinosis that showed a significant decline in the number of deaths between 1979 and 2014.[33] While the number of cases may have decreased in the United States, increases throughout the rest of the world, especially in countries where cotton industries have grown (such as India, Pakistan, Nepal, Sri Lanka, and Bangladesh) are not surprising. Besides cotton-based industries, flax, hemp, and jute exposures may also cause byssinosis.

Despite modernization and better work environment, byssinosis is still common. The prevalence of byssinosis in textile workers is difficult to estimate, especially since the timing of the survey may affect the prevalence estimate. For example, in a cotton textile worker cohort in Shanghai, China, examined from 1981 to 1996, 15.3% of workers reported byssinosis in the most recent survey (after 15 years) versus 7.6% at baseline.[34] Another study in Pakistan showed that 26.6% of workers had frequent sputum production, and 16.7% of works had frequent cough.[35] Not all workers in the cotton industries have the same risk of developing bronchitis. Ginning, opening, or carding work carries a higher risk than other jobs. Cleaning work, such as performed by strippers and grinders (who maintain the carding machinery), carries a particularly high risk for developing byssinosis.

■ Risk Factors

The length of employment and the intensity of cotton dust exposure are well-known risk factors for developing higher grades of byssinosis. Beyond cotton dust exposure itself, the endotoxin level in the workplace can potentiate the pathogenesis of the disease. In a 15-year Chinese longitudinal cohort study, endotoxin was an independent predictor of FEV_1 and FVC decline among cotton workers.[34]

Gene–environmental interaction also may play a role in disease pathogenesis. Workers with an A allele of TNF–308G/A polymorphism have a greater FEV_1 decline with endotoxin exposure.[36] Cigarette smoking also has been thought to have an additive effect with cotton exposure in developing byssinosis.[37] This may also explain why in southern Asia byssinosis is more prevalent, since workers in these countries also smoke heavily, which may exacerbate symptoms.

■ Mechanism and Pathogenesis

Cotton dust alone may cause airway inflammation—a phenomenon that can be seen in a tobacco smoker's airways; however, the endotoxin level in cotton dust or work environment may also play an important role in the pathogenesis of byssinosis. Endotoxin is a lipopolysaccharide found in gram-negative bacteria. The gram-negative bacterial endotoxins in cotton dust are probably the causative agent for airway obstruction and inflammation.[34,38] Findings supporting this conclusion include the following: (1) endotoxin can be detected in cotton dust; (2) animal and human studies support the concept that endotoxin inhalation can induce airway inflammation; and (3) ambient concentrations of endotoxin correlate with reduction in airway flow rates.[39]

■ Clinical Presentations

Patients usually present with frequent cough, chest tightness, dyspnea, and wheezing. Symptoms mostly happen within a few hours of exposure or re-exposure ("Monday fever"). Schilling first classified the severity of byssinosis solely based on symptoms, designating grades 0 to 3, with grade 3 the most severe.[40] The classification is shown in Table 88-5. In 1983, the World Health Organization proposed a modified classification system that incorporates spirometry; however, the revised classification has not been broadly adopted in current practice.[41]

TABLE 88-5 Clinical Grading of Byssinosis as Proposed by Schilling

Grade 0	No symptoms on first day of work
Grade 1/2	Occasional chest tightness or irritation of respiratory tract on the first workday of week
Grade 1	Chest tightness on every first day of work week
Grade 2	Chest tightness on first and other days of work week
Grade 3	Chest tightness on first and other days of work week and physiologic evidence of permanent disability

Reproduced with permission from J. Allen D. Cooper.

■ Diagnosis

Unfortunately, there are no specific diagnostic tests for byssinosis. A detailed occupational history that establishes the timing of exposure and the onset of symptoms is essential. Physical examination may show fine basilar rales, and chest radiographs may show hyperinflation of the lung. However, these findings can also be seen in asthma or other pneumoconioses. Pulmonary function tests before, after, and between work shifts may be very helpful (e.g., a decline in FEV_1 noted on the day of return to work after an absence[42]).

■ Management and Prognosis

The most important elements in management are removing the symptomatic worker from the work environment and dust exposure reduction,[42] which can be done through a change in cotton processing (e.g., steam-cleaning cotton while it is still in the bale). Use of an inhaled bronchodilator with either short- or long-acting beta-agonist activity may improve respiratory symptoms. Treatment may be needed chronically. With severe and acute symptoms, a short course of corticosteroids may help. Most patients recover after the treatment and removal from exposure. For those patients with chronic cotton exposure, persistent airway inflammation may lead to obstructive lung disease.[43] Finally, in a 30-year longitudinal study of textile workers, cotton dust was found to be associated with increased cancer mortality, especially due to gastrointestinal cancer.[44]

OTHER ORGANIC DUST–RELATED DISEASES

Organic dust toxic syndrome (ODTS or pulmonary mycotoxicosis) results from exposure to mycotoxins or endotoxins.[45–47] The syndrome has been associated with exposure to grains, moldy hay, and cotton contaminated with the fungus *Fusarium*.[48] Symptoms of ODTS include fever, chills, dyspnea, cough, myalgias, and nausea that occur 4 to 6 h after exposure. Pulmonary function tests may show a restrictive ventilatory defect and a reduction in diffusing capacity. Desquamative interstitial pneumonitis also may be seen.[48] A specific clinical manifestation seen with grain dust exposures are skin reactions, which are not seen in byssinosis.[49]

OCCUPATIONAL EXPOSURE, COPD, AND CHRONIC BRONCHITIS

In the most recent American Thoracic Society and European Respiratory Society statement on COPD from 2019, the estimated occupational burden for COPD is 14% and 13% for chronic bronchitis.[3] Distinct from occupational asthma, COPD does not include a clinical subentity, such as "occupational COPD." This may be due to the fact that COPD develops slowly and is irreversible, even after avoidance of occupational exposure.[50]

Organic dust toxin syndrome and byssinosis are sometimes misclassified as COPD; however, work-related airflow limitations often have asthma-like symptoms and may become poorly reversible with chronic exposure.[50] A distinction between lung disease related to occupational exposure to organic dust and COPD is important.

In addition to COPD, emerging literature addresses occupation-related chronic cough or chronic bronchitis, especially in the context of the collapse of the World Trade Center in 2001. Chronic bronchitis has been reported in firefighters and first responders in the aftermath of collapse of the World Trade Center.[51,52] Several studies have found an association between chronic cough and occupational exposure in mines, cement workers, construction workers, and those employed in farming and the food, chemical, and wood industries.[53]

The diagnosis of occupation-related COPD or chronic bronchitis can be difficult, as the two diseases can also be caused by nonoccupational factors, such as tobacco smoking—the predominant risk factor for COPD. As noted previously, occupational risk is likely an independent risk factor, and the physician must take a detailed occupational history to explore the potential occupational etiologies of the patient's obstructive airway disease or chronic cough. Identifying occupational risks early may prevent worsening of the disease and initiation of a proper public health surveillance program and worker's compensation.

CHAPTER 89

Indoor and Outdoor Air Pollution

Coralynn Sack
Joel D. Kaufman

INTRODUCTION

Exposure to air pollution is ubiquitous and a major cause of global morbidity and mortality. This chapter provides a broad introduction to indoor and outdoor air pollution, beginning with a brief review of the emergence and recognition of air pollution as a major public health concern. The chapter then reviews general principles and concepts related to inhalation injury, exposure, and health outcomes. The health consequences of indoor and outdoor air pollution are covered separately, although this distinction is largely artificial, given the significant overlap in exposure between pollutants found in indoor and outdoor locations. While the emphasis of the chapter is on respiratory health effects, the extrapulmonary effects of air pollutants are briefly discussed. The chapter concludes with a discussion of susceptible populations and different control strategies, aimed both at public health and individual levels.

OVERVIEW

Air pollution is now considered the largest environmental cause of disease and premature death in the world, responsible for an estimated seven million deaths per year.[1] Exposure to air pollution is a significant cause of cardiopulmonary disease and likely increases the risk of neurodevelopmental disorders, poor birth outcomes, metabolic disease, and malignancy. While a global problem, air pollution disproportionately affects the poor with the highest exposure levels occurring in low- and middle-income countries. Several of the principal air pollutants also act as greenhouse gases, contributing to global warming and the additional health risks associated with climate change.

The sources and concentration of pollutants have changed throughout history, as societies develop and as the climate warms. The use of fire for heating and cooking created exposure to smoke, a problem that persists for the billions of people who still use biomass fuels today. The rise of cities concentrated the emissions of pollutants from dwellings and manufacturing facilities within restricted locales. Industrialization introduced localized or point sources of pollution, such as power plants, which generate immense emissions of combustion byproducts in areas where people live and work. During the 20th century, mobile sources, including cars, trucks, and other fossil fuel–powered vehicles, created a new type of pollution: photochemical pollution, or “smog.” The unprecedented growth of some urban areas to form “megacities,” such as Mexico City, São Paulo, and Shanghai, has led to unrelenting air pollution from massive vehicle fleets, standstill traffic, polluting industries, and power plants.

Increasingly, there is recognition that the problem of air pollution extends into the indoor environment. In low- and middle-income countries, exposure to smoke from biomass fuel combustion for indoor cooking and heating is still widespread. In the more developed countries, indoor pollutants can be either generated by human activities or released from building and construction materials. Buildings designed to optimize energy conservation by reducing the exchange of indoor and outdoor air can seal pollutants within and result in unhealthy concentrations.

For centuries, people have recognized that air quality has health consequences. Classical writings from Roman times contain references about poor air quality linked to health. In the late 1200s, King Edward I attempted to ban the burning of “sea coal” in open furnaces to limit the emissions of sulfurous smoke.[2] However, the modern era of air pollution research and regulations did not begin until the mid-20th century, when dramatic pollutant events in the United States and England caused a clear increase in mortality. Perhaps the most striking of these episodes was the London Fog of 1952, when a temperature inversion caused the accumulation of a dense layer of coal-related toxic air, resulting in more than 3000 excess deaths observed over the next month. More recent analyses suggest that the actual mortality toll attributable to the event was probably closer to 12,000 and was associated with a persistent increase in death for more than 1 year.[3]

These catastrophes sparked the passage of environmental legislation, including the Clean Air Acts of 1956 and 1968, which laid the foundation for modern control measures.[4] They also motivated research to characterize pollutants, toxicologic investigations aimed at uncovering biologic mechanisms, and epidemiologic studies to quantify health effects in the community. These research approaches are fundamental to our understanding of the public health impact of air pollution and have resulted in a large body of scientific evidence over the past half century. The synthesized findings from this research have formed the foundation for a legal framework of regulations to limit emissions and control concentrations of key pollutants in outdoor air. These evidence-driven regulations have had substantial impact on air quality in the United States, driving down levels of the most prominent pollutants (Fig. 89-1).[5]

In spite of these improvements in air quality, air pollution remains a significant public health concern. Epidemiologic studies show that adverse health effects still occur at concentrations frequently observed and at the upper end of the range of the National Ambient Air Quality Standards (NAAQS). In addition, billions of people worldwide are exposed to levels of ambient air pollutants far above recommended levels.[6] As a consequence of the anthropogenic release of pollutants into the atmosphere, climate change has become an increasingly dire issue with a multitude of direct and indirect consequences.[7] Indoor air pollution continues to be a concern and, unlike outdoor air pollution, is not regulated by the EPA.

The literature on air pollution is now voluminous and has been published in a broad array of journals and technical reports. Of necessity, this chapter is selective in its review and emphasizes the most relevant findings for clinicians as well as newer literature. The documents prepared by the EPA on the six “criteria” pollutants (sulfur dioxide [SO_2], particulate matter, NO_2, carbon monoxide [CO], ozone [O_3], and lead) offer encyclopedic reviews that are updated periodically (Table 89-1). Key documents on specific pollutants are cited within the appropriate sections of this chapter.

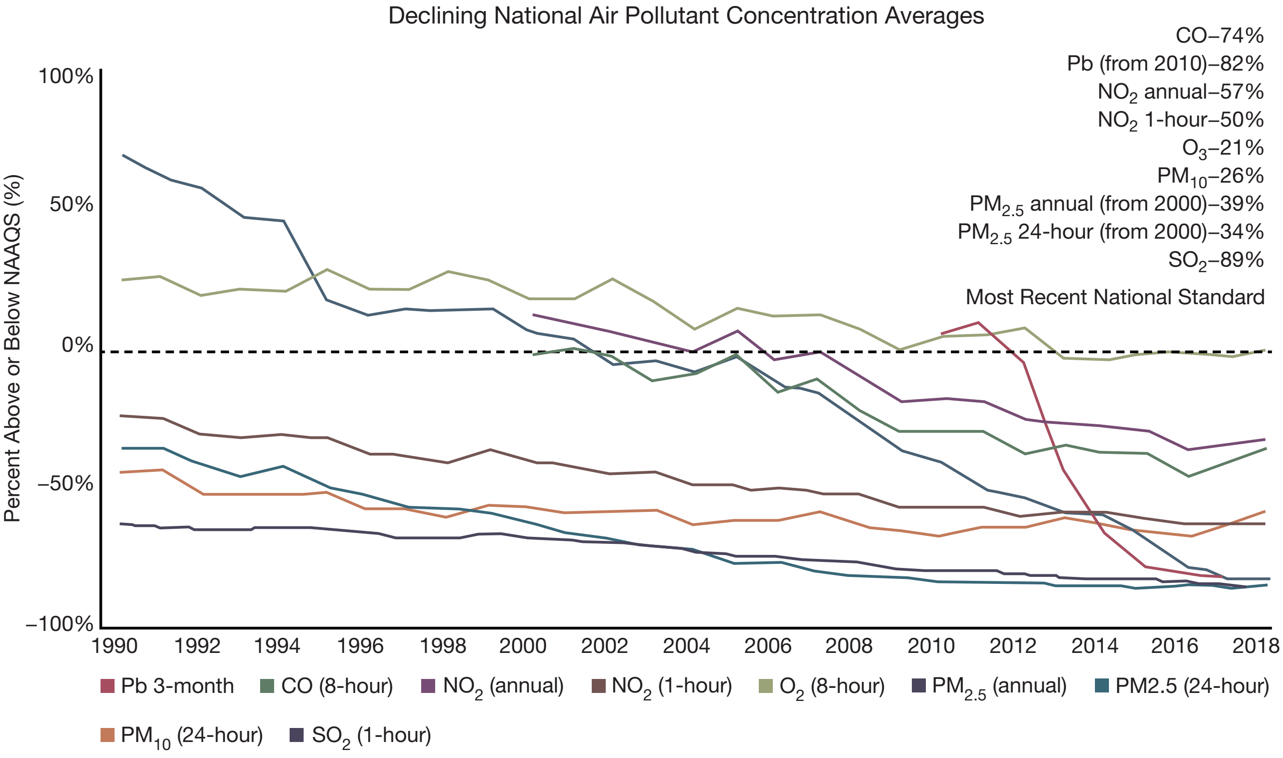

Figure 89-1 Comparison of national levels of the six common pollutants to the most recent National Ambient Air Quality Standards, 1990–2018. National levels are averaged across all monitors with complete data for the time period. *(Reproduced with permission from Our Nation's Air. Air Quality Improves as America Grows. Status and Trends Through 2019. https://gispub.epa.gov/air/trendsreport/2020.)*

TABLE 89-1 Criteria Pollutants, Sources, and National Ambient Air Quality Standards (NAAQS)

Pollutant	Outdoor Sources	Primary Standards	Averaging Time[a]
Sulfur dioxide	Coal and petroleum combustion, smelting, and other manufacturing	75 ppb	1 h
PM_{10}	Coal and petroleum combustion, vehicles, industry, surface dust	150 μg/m^3	24 h
$PM_{2.5}$	Fuel combustion from automobiles, power plants, wood burning, industrial processes, and diesel-powered vehicles	35 μg/m^3 12 μg/m^3	24 h Annual (arithmetic mean)
Nitrogen dioxide	Motor vehicles, coal and petroleum combustion, industry	100 ppb 53 ppb	1 h Annual mean
Carbon monoxide	Motor vehicles, coal and petroleum combustion	35 ppm (40 μg/m^3) 9 ppm (10 μg/m^3)	1 h 8 h
Ozone	Secondary formation from NO_2 and hydrocarbons	0.070 ppm	8 h
Lead	Gasoline, lead-containing dust	0.15 μg/m^3	Rolling 3-month average

[a] *Averaging time denotes the defined time period over which concentration is measured and averaged.*

GENERAL PRINCIPLES AND CONCEPTS

Air pollution is defined as the presence of hazardous chemicals or compounds in the air, at levels that pose a threat to human health, damage other living organisms, or adversely affects the natural environment.[8] In humans, adverse responses to air pollutants are a reflection of the exposure, target site of injury, and downstream effects of pollutants (Fig. 89-2). This section of the chapter covers principles of inhalation injury, proposed mechanisms of action, and the related spectrum of adverse health effects. It also reviews the research methods that have been developed to characterize the effects of air pollutants.

■ Principles of Inhalation Injury

Atmospheric pollutants exist as a complicated mixture of gaseous, liquid, and solid particles. The health effects from inhalation depend on a complex interplay between host and exposure characteristics. The substance's physical state, concentration, solubility, and aerodynamic dimensions partially determine the site of deposition and retention within the lung.[9] Water-soluble gases, such as SO_2, are almost completely removed in the nasopharynx while less soluble gases, such as NO_2 and O_3, can penetrate deep within the lung. Smaller particles (0.1–5.0 μm) are more likely to reach the alveoli, whereas larger particles (≥10 μm) are typically trapped and removed by the mucus and cilia of the upper respiratory tract. Ultrafine particles ($PM_{0.1}$) can pass through the alveolar–capillary membrane to reach the bloodstream and travel to other end organs.

The rate and depth of inhalation also greatly affect the total dose of pollutants delivered to the lung. Exercise increases the dose by directly increasing minute ventilation and by stimulating a switch from nasal to oral breathing, bypassing more efficient pollutant removal in the nasal passages. Airway anatomy, including branch structure and caliber, contribute by influencing aerodynamic

transportation and deposition mechanics in the lungs. Other factors that impact susceptibility include genetic factors related to oxidative stress and inflammation, the ability to clear substances from the respiratory tract, the presence of other comorbidities, and effects of concomitant exposures such as tobacco smoke.

The physiologic mechanisms by which inhaled gases and particles cause injury are diverse and only partially understood. Deposited particles can cause direct damage, activate sensory receptors, induce reactive oxygen species and inflammatory responses, or cross the permeable epithelial barrier to enter the systemic circulation. The oxidant gases O_3 and NO_2 also cause inflammation of the respiratory epithelium, presumably through the production of toxic oxidant species and release of potent mediators.

Oxidative stress occurs when the body's innate antioxidant capabilities are overwhelmed by reactive oxygen species, resulting in lipid peroxidation and activation of proinflammatory signaling, such as mitogen-activated protein kinase (MAPK) and nuclear factor–kappa beta (NF-κβ). This cascade can result in increased cytokine production as well as elevations in CRP, fibrinogen, and circulating leukocytes with both pulmonary and systemic effects. Epigenetic changes mediated through DNA methylation result in modified gene expression and activity. Ultimately, these can contribute to an alteration in endothelial function, platelet activation, autonomic dysregulation, and changes in the innate and adaptive immune system (Fig. 89-3).

ADVERSE HEALTH EFFECTS OF AIR POLLUTION: CLINICAL AND PUBLIC HEALTH CONCERNS

The spectrum of adverse effects of air pollution is broad, ranging from the consequences of acute, dramatic exposures to more subtle effects on disease risk resulting from chronic exposures. This spectrum has been conceptualized as a pyramid with mortality at its tip and an increasingly common set of morbidities as the base.[10]

To interpret the scientific evidence on the effects of air pollution, clinicians need a framework for determining whether an effect is "adverse." If a broad construct of health is used that includes a state of well-being as a component, adverse effects of air pollution include not only clinically evident disease but also more subtle symptom responses and physiologic effects that may compromise well-being or increase the risk of disease. In a 2016 report, a committee of the American Thoracic Society (ATS) revised guidelines for defining adverse health effects in epidemiologic studies of air pollution.[11] The committee recommended that various biomarkers, intermediary outcomes, and preclinical diseases should be labelled as adverse health effects when they are linked to a clinical condition, pathologic change, or pathway to these changes. As an example, they cite the transient increase in sputum leukocytes observed after ozone exposure. While not deleterious by itself, this finding should be considered as adverse when interpreted in the context of its known association with airway inflammation, decrement in lung function, and increased risk of exacerbation in individuals with chronic respiratory disease (Table 89-2; Fig. 89-4).

■ Concepts of Time–Activity and Total Personal Exposure

Definitions of concentration, exposure, and dose are fundamental to considering the health effects of air pollution and steps used to reduce risk.[12] *Concentration* refers to the amount of material present in air. *Exposure* constitutes contact with a material at a portal of entry into the body—the respiratory tract, gastrointestinal tract, and skin—and is calculated as the unit of concentration multiplied by time. In the lung, exposure would constitute the time spent in contaminated air. *Dose* refers to the amount of material that enters the body; *biologically effective dose* is the amount of material reaching target sites for injury—for example, the mass of respirable particles delivered to the small airways.

When considering health impacts, *total personal exposure* to a pollutant is the relevant index of exposure, not the exposures received separately within indoor and outdoor environments. The total personal exposure to a pollutant can be conceptualized as the sum of time-weighted average pollutant concentration in different

"microenvironments."[13] Microenvironments are locations that have relatively constant levels of pollutants during the time spent there. The principal microenvironments contributing to total personal exposure are either those with relatively high concentrations or in which relatively large amounts of time are spent. For example, for particulate matter exposure, key microenvironments may include an office where smoking is allowed or the indoor residential environment. New sensing approaches are facilitating refined studies of activity levels and air pollution concentrations, which will help clarify an understanding of where and when the most-risky exposures take place.

Studies of time use in a number of countries show that people spend an average of 65% to 75% of their time inside their residences, and more than 90% of their time indoors, when including contributions from home, work, and recreational activities.[14] Consequently, personal exposures to many pollutants take place largely in indoor microenvironments. However, many pollutants generated by outdoor sources can penetrate indoors and contribute to the indoor microenvironment. Other pollutants, such as O_3, have low indoor levels so that outdoor exposures are the predominant determinants of personal dose.

■ Research Approaches to Air Pollution

Our understanding of the health effects of air pollution derives from a multipronged research approach, aimed at characterizing atmospheric pollutants and exposures, in vitro and in vivo toxicologic studies, and epidemiologic studies of "real-world" effects. These different approaches are complementary, each with their own advantages and disadvantages. Together, they provide the evidence used to define threshold levels for adverse effects due to air pollutants and are the basis on which air pollution standards are set.

A joint ERS/ATS policy statement: what constitutes an adverse health effect of air pollution? An analytical framework. Eur Respir J. 2017;49(1):1600419.)*

There is a significant body of literature on the physical and chemical properties of the different air pollutants. Exposure assessment has emerged as a distinct research discipline that uses questionnaires to capture activities and time use, personal and area monitoring of air pollution levels, statistical models to estimate exposures, and sophisticated biomarkers of exposure and dose.[13] New high-throughput technologies are being developed that will facilitate data-rich measurements of "the exposome," conceptualized as the totality of exposures that individuals experience over their lifetime.

Toxicologic studies are useful to characterize the hazards of air pollutants, explore pathophysiologic mechanisms, and assess patterns of injury and disease risk. In vitro studies of cell cultures, including human respiratory epithelial and alveolar cells, allow for rigorous control of experimental conditions to study biologic pathways of injury. Predictive toxicology methods that leverage advances in systems biology, engineered tissue, and mathematical modelling have the potential to rapidly identify and characterize emerging toxins.

Animal studies can be conducted in both healthy and diseased animals over a range of well-defined exposure levels and conditions. This allows the assessment of serious and permanent health conditions that are not possible in human studies. Animal studies also provide important insights into the impact of pollution on lung structure, both at the earliest signs of injury and at end stages of disease. By using larger numbers of animals and sensitive species or models of disease, animal toxicology studies can increase the likelihood of detecting adverse effects.[15] Despite these advantages, large interspecies variations can make findings difficult to extrapolate to human exposure and disease.[16]

In controlled human-inhalation exposure (CHIE) studies, volunteers are intentionally exposed to pollutants in controlled experimental conditions, such as an exposure chamber or sealed room. To be ethically acceptable, these studies are of brief duration and limited to levels of exposure to produce only acute fully transient effects. CHIE studies have the advantage of allowing a randomized controlled design and isolating the effects of specific laboratory-generated pollutants or mixtures, such as O_3, PM, or diesel exhaust particles (DEP). In addition to healthy volunteers, sensitive populations can also be selected for investigation, such as individuals with asthma, chronic obstructive pulmonary disease (COPD), coronary artery disease, or specific genetic polymorphisms. By producing transient changes in biomarkers, physiologic parameters, or other subclinical endpoints, CHIE studies have helped to elucidate mechanisms of injury, understand concentration-response functions in the species of primary interest, and inform air-quality standards.[17]

Epidemiologic studies use statistical methods to analyze the association between "real-world" exposure to air pollution and various health effects.[13] The findings of epidemiologic studies of air pollution have direct public health and regulatory relevance. Exposure concentrations and mixtures are representative of those received in the community. A range of participants can be studied, from those who are expected to be most susceptible or vulnerable to a more representative selection of the general population.

There are some limitations to observational studies, including the difficulty in concluding that an observed relationship is caused by the exposures. Epidemiologic studies having inadequate sample size and, therefore, limited statistical power, may supply imprecise and uninformative estimates of risk and may not be able to answer public health questions. *Confounders* are factors that are correlated with air pollution, the exposure of interest, and are also predictors of the health outcome. If these factors are not appropriately measured and adjusted for in the analysis, the results can be biased.

Exposure to pollutants is also difficult to measure accurately in epidemiologic studies, and it is often inferred from a participant's home address through a variety of different approaches. These estimates range in accuracy, from using pollutant levels from the nearest regulatory air quality monitors to calculating exposure via sophisticating spatiotemporal models. All these techniques can have some error, both random and systematic, that may not reflect individual exposure through day-to-day activities. Exposure to pollutants rarely occur singly, and disentangling the effects of individual pollutants from complex mixtures is challenging. Because many pollutants track together, adjusting for co-pollutants within statistical models is limited by collinearity.

OUTDOOR AIR POLLUTION

This section begins with a review of the sources and then considers the effects of the principal outdoor pollutants, grouped according to their designation by the EPA (Tables 89-1 and 89-3).

TABLE 89-3 Criteria Pollutants, Key Mechanisms, and Established Health Effects

Pollutant	Key Mechanisms	Established Health Effects
Sulfur dioxide	Highly soluble Generation ROS Activation sensory nerves	Upper airway injury Bronchoconstriction Increased asthma incidence and exacerbations
PM_{10}	Deposits in upper airway	Increased respiratory symptoms Asthma and COPD exacerbations
$PM_{2.5}$	Deposit in lower airway/alveoli Direct epithelial injury Generation ROS Translocation to bloodstream	Increased incidence and exacerbation of chronic lung diseases Reduced lung function Lung cancer Increased cardiopulmonary mortality Increase in neurocognitive disease
Nitrogen dioxide	Less soluble Oxidant gas	Bronchial and bronchiolar injury Impaired lung defense Enhanced response to allergens
Carbon monoxide	High affinity with hemoglobin Tissue hypoxia	Increase myocardial ischemia Neurologic effects
Ozone	Less soluble Highly reactive Simulation C-fibers	Bronchial and bronchiolar injury Reduced lung function Asthma and COPD exacerbations

Overview: Sources and Classification of Outdoor Air Pollution

Outdoor air pollutants originate from many diverse sources that can be classified as either natural or anthropogenic. While many naturally occurring pollutants, such as pollen and fungi, have well-recognized pulmonary effects, this chapter focuses predominantly on pollutants that arise from human activities. The major causes are fossil fuel combustion from mobile sources (such as motor vehicles), heat and power generation, industrial facilities (such as oil refineries and chemical manufacturing), municipal and agricultural waste sites, and residential cooking and heating.

In the United States, the principal outdoor pollutants are classified within the framework provided by the Clean Air Act, which identifies two sets of air pollutants, "criteria" pollutants (Table 89-1) and "toxic" air pollutants. The term *criteria* refers to the standard-setting process for these pollutants, which requires preparation of a criteria document reviewing all relevant evidence every 5 years. The criteria pollutants include primarily combustion-related pollutants: sulfur dioxide (SO_2), nitrogen dioxide (NO_2), particulate matter (PM), and carbon monoxide (CO); they also include the secondary pollutant ozone (O_3) and lead. The toxic pollutants are a diverse group of chemicals with serious health effects, including carcinogens, teratogens, and mucosal irritants. Examples of these pollutants are benzene, chlordane, ethylene oxide, hydrochloric acid, methane, parathion, propylene oxide, toluene, and vinyl chloride.

The regulations for these two groups of pollutants are designed to set maximum concentrations that provide an "adequate margin of safety" to the entire population, including those with heightened susceptibility. The National Ambient Air Quality Standards (NAAQS) sets standards for the six criteria pollutants, while the National Emissions Standards for Hazardous Air Pollutants (NESHAP) establishes maximum emission concentrations for the other toxic pollutants. Despite existing federal standards for ambient air quality, excesses are common in many areas of the country, particularly for O_3. Although the pollutants are considered in the following section on an individual basis, it should be re-emphasized that exposures of the population occur most often to mixtures, and synergy among individual pollutants may increase the effects of the mixture beyond the expected effect based on the components.

Outdoor Air Pollutants: Exposures and Health Effects

Important outdoor air pollutants are discussed individually below.

Particles

Perhaps the largest body of literature on the adverse effects of air pollution focuses on particulate matter (PM), which has repeatedly been shown to be associated with significant pulmonary morbidity and mortality as well as an increasing number of other extrapulmonary toxicities. PM refers to the diverse mixture of suspended liquid and solid particles found in the air and generated through a variety of anthropogenic and natural sources. Fossil fuel combustion and biomass burning accounts for approximately 85% of global ambient particles.[6] In urban areas, the most important contributors are fuel combustion for electrical production, industrial processes, and motor vehicle emissions. Particles can also arise from crushing/grinding processes or resuspension of crustal materials, such as road and tire byproducts, agricultural dust, and industrial waste sites.

The toxicity of PM likely reflects a combination of particle source, chemical composition, size, and shape. PM exists both as primary particle emissions from specific sources and as secondary compounds, formed through physical and chemical reactions in the atmosphere. Because of the diversity of sources, particles can have heterogeneous compositions that vary in both spatial and temporal dimensions. The pollutant mix reflects both local sources and those contributing to the regional background pollution (i.e., pollution generated elsewhere but transported to this and other locations via prevailing winds). In the Eastern United States, for example, much of the regional background of $PM_{2.5}$ comes from transport of power plant emissions from the central portion of the country. Hypotheses proposed on the chemical determinants of particle toxicity have focused on issues related to surface acidity, ability to exert oxidative stress, content of transition metals, organic compounds on particles (e.g., diesel particles) and presence of biologically derived agents, such as pollens or endotoxin.[18]

PM is typically divided into size categories based on mean aerodynamic diameter, as PM_{10} (particles with aerodynamic diameter <10 μm), coarse particles or $PM_{2.5-10}$ (aerodynamic diameter between 2.5 and 10 μm), fine particles or $PM_{2.5}$ (aerodynamic diameter <2.5 μm), and ultrafine particles (UFP, particles with aerodynamic diameter <0.10 μm, sometimes also referred to as nanoparticles) (Fig. 89-5). As reviewed earlier in the chapter, particle size is a determinant of inhalability and penetration within the lung. Particles larger than 10 μm tend to deposit in the nasopharynx while particles smaller than 2.5 μm can reach the gas-exchange region of the lung. The smallest particles (generally <200 nm) can be translocated across the respiratory epithelium and have been identified in multiple other organs, such as the CNS and placenta.[19,20]

The limitations of national air pollution monitoring programs make it difficult to discern differences in health effects among PM size fractions. The most complete monitoring data exist for $PM_{2.5}$, for which extensive monitoring was launched in 1999 in the United States; limited coarse PM monitoring was instituted in 2011, and there is no current national monitoring for UFP. Consequently, most epidemiologic studies have focused on PM_{10} or $PM_{2.5}$, with the strongest effects attributable to $PM_{2.5}$ exposure.

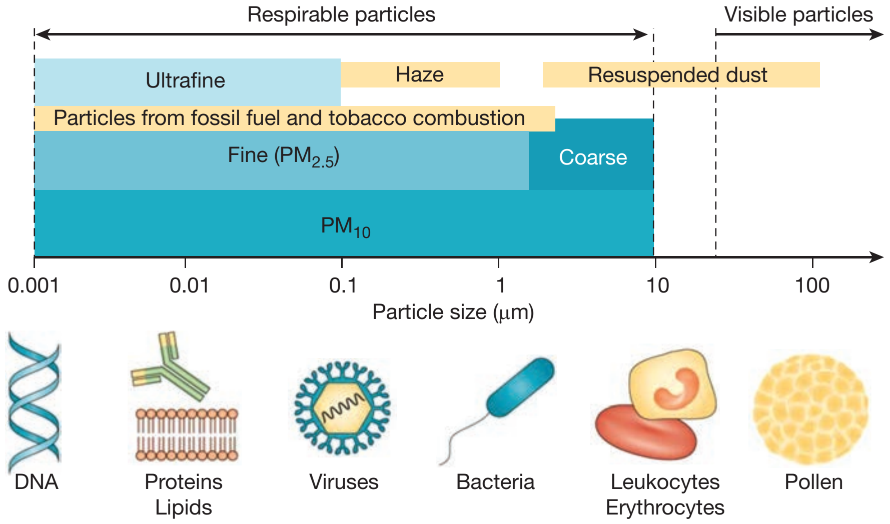

Figure 89-5 Size categorization of particulate matter. *(Reproduced with permission from Cosselman KE, Navas-Acien A, Kaufman JD. Environmental factors in cardiovascular disease. Nat Rev Cardiol. 2015;12(11):627–642.)*

Upon deposition, PM can cause direct epithelial injury, activate irritant receptors, generate reactive oxidative stress, and stimulate pulmonary inflammation and injury. Alveolar macrophages ingest PM, leading to the release of interleukin 6 (IL-6) and other proinflammatory cytokines. The accumulation of these carbon particles in macrophages can also overload the cells, resulting in impaired function and the buildup of anthracotic deposits in the lymphatic system and lung interstitium. UFP may have higher oxidative potential than other size fractions due to their increased surface area with a greater concentration of reactive oxygen species. In addition, UFP can cross the epithelial border to enter the bloodstream, and ultimately deposit in other organs where they cause disease direct damage or localized inflammation. The downstream effects of these interconnecting pathways can result in local and systemic inflammatory responses, altered immunity, endothelial dysfunction, and platelet aggregation.

Exposure to PM is a well-established cause of adverse respiratory outcomes. Both short-term and chronic exposures can result in decreased lung function, exacerbation of chronic lung disease, and increased morbidity and mortality from respiratory diseases. As opposed to the immediate effects associated with gaseous pollutants, the acute effects of PM often lag 0 to 5 days after exposure. Toxicology studies with animal models demonstrate impaired lung development with both pre- and postnatal exposure, allergic phenotypes, and increased airway hyperresponsiveness. While associations are strongest and most consistent with exposure to $PM_{2.5}$, short-term exposure to PM_{10} also is associated with ED visits and hospitalizations for worsening respiratory disease.

The global burden of disease resulting from PM exposure is significantly higher for cardiovascular rather than respiratory diseases, due to the higher underlying incidence of cardiovascular disease. While the proposed pathways that mediate this response are complex and beyond the scope of this chapter, they involve activation of the autonomic nervous system, altered endothelial function, accelerated atherosclerosis, and decreased LV contractility.[21] PM is strongly associated with increased risk of myocardial infarction, arrhythmia, stroke, and hospital admission for congestive heart failure. Multiple studies have demonstrated that $PM_{2.5}$ results in excess cardiovascular mortality, even in areas where levels are below 20 μg/m^3 or even less than 12 μg/m^3.

In addition to the clear risk of increased cardiopulmonary disease, PM is also associated with a variety of other extrapulmonary diseases in epidemiologic studies. In particular, there is a growing body of evidence demonstrating that PM has central nervous system effects, including neurodegenerative disease, cognitive effects, and impairment in neurodevelopment.

Although there is some uncertainty regarding the shape of the dose–response curve, current evidence supports that there is no threshold for adverse effects. Studies to date suggest a nonlinear dose–response relationship, with a sigmoidal or S-shaped curve: the lowest concentrations elicit a less toxic response, followed by a steeper relationship over which smaller increases in concentration cause more dramatic effects, and finally a leveling off at high concentrations.[22] These findings suggest that the present NAAQS for particulate matter may not protect against adverse health effects with the "adequate margin of safety" mandated by the Clean Air Act.

Nationally, PM levels have declined by nearly 10% since 1999 with the largest reductions in the regions of the country that initially had the highest concentrations, such as the Southeast, Southern California, and industrial regions of the Northeast.[23] A study analyzing this improvement in air quality demonstrated a concomitant increase in life expectancy of approximately 0.61 years for each 10-μg/m^3 reduction in $PM_{2.5}$.[24] Other observational studies have reported similar findings with improvement in morbidity and mortality accompanying reductions in PM.[25]

Sulfur Dioxide

The major source of sulfur oxides is the combustion of sulfur-containing fuels, mainly coal-fired power production, crude petroleum, and smelting of some ores. While there are naturally occurring sources as well, these contribute to less than 1% of ambient air concentrations, except in areas such as Hawaii where volcanic emissions are important.[26] Most exposure to SO_2 in outdoor air results in simultaneous co-exposure to other combustion-related pollutants, including NO_x and particles. Tall smokestacks for power plants, used to control local pollutant concentrations, release sulfur oxides and NO_x high into the atmosphere, where residence time is prolonged. Through a series of oxidizing chemical reactions, sulfur oxides and NO_x form sulfuric acid and nitrate particles, which are subsequently converted to clouds, fog, and eventually acid rain.[27] These pollutants can undergo long-range transportation, creating regional air problems across large portions of Central and Northeastern United States.

Due to changing patterns of fuel use and regulations, such as the Environmental Protection Agency's Acid Rain Program, which mandated ultra-low-sulfur fuels and improved controls of smokestack discharges, emissions of SO_2 have declined by approximately 79% from 1990 to 2014.[26] While there has been significant progress in reducing national emission, local sources, such as power plants or metal processing facilities, can still result in plumes with high exposures and significant spatial heterogeneity.

SO_2 is a water-soluble gas that is effectively absorbed by nasal passages and upper airway. The fate of SO_2 in the upper airways is dependent upon a series of chemical reactions, resulting in the formation of sulfite and S-sulfonates, which are readily absorbed into the blood. Overall sulfite levels in the body are heavily influenced by endogenous production and by the ingestion of food with sulfur-constituents. Consequently, inhaled SO_2 contributes little to the total body dose and most adverse health effects are related to localized effects within the respiratory tract. With exercise, there is an increase in the inhaled dose to the lower airways, both due to the rise in minute ventilation and the switch from nasal to oral breathing.

SO_2 inhalation results in immediate bronchoconstriction in both healthy adults and in individuals with asthma. The response is primarily mediated by the activation of sensory nerves, such as the vagus nerve.[28] In asthmatics, bronchoconstriction occurs at a lower concentration through an additional pathway that involves allergic inflammation. Human controlled exposure studies demonstrate that deep breathing of SO_2 for 5 to 10 min results in lung function decrement and respiratory symptoms.[29] While evidence is not definitive, there is also some suggestion that these acute exposures could lead to extrapulmonary effects from stimulation of sensory nerves resulting in changes to heart rate variability.[30] The evidence documenting an association between short-term exposures and respiratory effects motivated the current NAAQS SO_2 primary standard with 1-h average concentration of 75 ppb.[26]

Chronic respiratory effects also have been observed in animal studies, where repetitive exposure is associated with airway inflammation, remodeling, and airway hyperresponsiveness. These mechanisms suggest that SO_2 exposure can lead to both new incident disease and worsening of pre-existing asthma.

Although it is difficult to separate out the effects of SO_2 exposure from co-pollutants, epidemiologic studies have mirrored the effects observed in toxicology experiments. Acute exposure to SO_2 is associated with urgent care visits and hospital admissions for respiratory illnesses, particularly in children, asthmatics, and the elderly. Some studies have also suggested that long-term exposure is associated with incident asthma. Epidemiologic studies from Hong Kong have examined the consequences of a major reduction in sulfur content in fuels over a very short period of time. The investigators found an associated substantial reduction in health effects, specifically for childhood respiratory disease and all-age mortality outcomes.

Nitrogen Dioxide

NO_2 is the criteria pollutant regulated by the EPA that serves as an indicator of the larger group of reactive gases, collectively known as oxides of nitrogen (NO_x). This group of gases are primarily emitted in the form of nitrogen monoxide (NO) but rapidly react with oxygen to form NO_2 and other oxidized nitrogen-forming compounds. NO_x is readily transformed to secondary pollutants and is a precursor for O_3.

NO_2 is considered a proxy of near-road pollutants, as motor vehicle emissions are the largest contributor to outdoor concentrations within the United States. Other traffic-related pollutants, such as particulate matter, black carbon, and CO, highly correlate with concentrations of NO_2, which can make it difficult to separate out effects from these co-pollutants. Other sources include power plants, industrial facilities, wildfires, and other forms of transportation. Due to variation in the emission source and photochemical transformations, NO_2 has significant spatial and temporal variation within neighborhoods. Levels largely vary along with distance to road and are highest at times of peak traffic and in the winter.

In addition to outdoor sources, substantial personal exposure in the United States occurs in indoor microenvironments contaminated by unvented gas stoves and space heaters. These exposures can be higher than those typically found in outdoor air and are discussed in more detail in the subsequent section on indoor air.

NO_2 is an oxidant gas of low solubility that penetrates to the small airways and alveoli of the lung. Within the airways, it hydrolyzes with water on mucosal surfaces to form nitric and nitrous acid, which can lead to direct damage of the epithelial border, free radical generation with local and systemic inflammation, alteration of immune function, and impaired lung defenses.[31] After high-level acute exposures—such as those seen in industrial settings—NO_2 can cause acute pulmonary edema, ARDS, and subsequent bronchiolitis obliterans (Chapter 90). At the much lower concentrations observed in the typical indoor and outdoor environment, NO_2 can result in respiratory symptoms, increased airway hyperresponsiveness, and the development of allergic responses.

Data from human controlled-inhalation studies demonstrate that NO_2 can cause increased airway hyperresponsiveness in asthmatics within 1 h of inhalation. Combined with results from epidemiologic studies, this supports the evidence that acute exposure to NO_2 is a risk factor for asthma exacerbations, respiratory infections, and other adverse pulmonary outcomes. During the EPA's last review of NO_2 in 2016, they established a new 1-h standard for daily maximum NO_2, reflecting the consistent evidence of these acute adverse effects.[32]

There is also evidence that chronic exposure is associated with incident asthma. An increasing number of studies also suggests an association between NO_2 exposure and cardiovascular disease, adverse birth outcomes, diabetes, and total mortality. Individuals with asthma, children, and the elderly are most susceptible to health effects of exposure.

Ozone

Ground-level, or tropospheric, O_3 is a secondary pollutant produced by the action of sunlight on NO_x and other carbon-containing compounds, such as VOCs, CO, and methane. It is the primary component of smog, the photochemical pollution that reduces visibility in many urban and mountainous areas. Ground-level O_3 is distinct from stratospheric O_3, which is found higher in the atmosphere—above 10 km (6 miles)—and has the beneficial effect of acting as a protective layer, blocking the surface of the Earth from UV radiation.

Anthropogenic emissions, particularly from motor vehicles, are the most significant precursors of ground-level O_3, although there are some contributions from natural sources, such as wildfires, biogenic emissions (e.g., vegetation-released isoprene), and stratospheric O_3 exchange. Given the role of sunlight and heat in its formation, O_3 levels are seasonal and generally highest in the afternoon, during the spring and summer months. One exception is that some western U.S. mountainous basins experience high concentrations in the winter, where snow creates temperature inversions that trap emissions from oil and gas activity close to the ground.

While U.S. anthropogenic emissions have decreased over the past 10 to 15 years, O_3 levels in many areas can still regularly exceed the NAAQS.[33] Due to high chemical reactivity, outdoor O_3 does not readily infiltrate into buildings. Indoor concentrations are largely driven by O_3-producing appliances, such as electrostatic or ionic air purifiers, some vegetable washers, and water treatment devices.

O_3 is a pungent, blue-tinged gas that is water insoluble but highly reactive. The nasopharynx and upper airway can remove approximately 50% of the inhaled dose, while much of the remaining gas is transported deep within the lungs to act at the centriacinar region, the junction between terminal bronchioles and the alveoli. Given its oxidant properties, O_3 reacts with lipids, proteins, and antioxidants in the epithelial lining, leading to oxidative stress, direct cellular injury, and altered cell signaling. Secondary oxidation products stimulate nociceptive pathways, which reduce lung function, cause pain with deep inhalation, and may contribute to bronchoconstriction. The downstream effects include activation of inflammatory responses, alteration of the epithelial barrier function, bronchial sensitization, and modified immunity.[34]

Animal toxicology, human controlled inhalation studies, and epidemiologic studies have demonstrated that acute exposure to ozone causes respiratory morbidity and mortality. Volunteers exposed to O_3 at concentrations that are often present during pollution episodes experience transient reductions in lung function. Normal subjects have a range of responsiveness that is broad but repeatable for individuals: for example, some individuals exposed to 80 ppb O_3 for 6.6 h with 5 h of moderate activity will have no response, while others demonstrate up to 50% decrease in FEV_1. While the reduction in lung function is largely reversible after exposure to O_3 ceases, there is evidence of a persistent inflammatory response and biochemical changes in BAL fluid for up to 18 h after acute experimental exposure. Epidemiologic studies have consistently documented an association between short-term concentration and a range of pulmonary outcomes, including increased respiratory symptoms, respiratory infections, and exacerbations of obstructive airway disease.

The progressive decrements in pulmonary mechanics during exposure, coupled with the persistent biochemical changes many hours after cessation of exposure, indicate the potential for chronic effects from repeated inhalation. Chronic, low-level exposures cause damage to the small airways of experimental animals, including airway remodeling, subtle fibrosis, and permanent structural alteration. While epidemiologic studies have been somewhat mixed, there is convincing evidence that long-term exposures are associated with new-onset asthma, progression of COPD, and respiratory mortality.[35]

There is also increasing evidence linking O_3 exposure to metabolic and cardiovascular morbidity and mortality. Animal studies demonstrate impaired fasting glucose, increased triglycerides, and hepatic gluconeogenesis through activation of central neuroendocrine stress responses. These changes provide a biologically plausible connection between O_3 exposure and worsening IHD/HF, myocardial infarction, and stroke.

Carbon Monoxide

CO is an invisible gas formed by incomplete combustion of fossil fuels and other organic materials. The most prominent outdoor source is vehicle exhaust, leading to highly variable outdoor concentrations that track with traffic patterns and density. Since the passage of the Clean Air Act, there has been more than an 80% decrease in ambient CO levels, predominantly reflecting controls on vehicle emissions.[36] The most significant sources of indoor CO, which are discussed in greater detail in the section entitled indoor air pollutants, are cooking stoves, heating devices, and tobacco smoke.

The toxicity of inhaled CO is related to its high affinity for hemoglobin, resulting in tissue hypoxemia. The binding of CO to hemoglobin as carboxyhemoglobin (COHb) displaces oxygen and causes an allosteric change in the hemoglobin molecule, which also reduces the ability of hemoglobin to offload oxygen to the peripheral tissues. The COHb complex is very stable with a half-life of 2.5 to 4 h, depending on ambient levels of CO, level of activity, and lung function. The rate of accumulation of ambient CO in the body above endogenous levels is affected by ambient CO concentrations, alveolar ventilation, lung diffusivity, total hemoglobin mass, and COHb level.[37] People with impaired gas exchange (e.g., persons with COPD) have compromised ability to excrete CO.

The level of CO in the blood is a useful biomarker of dose, and the health effects of exposure to CO can be related to COHb levels. In nonsmokers who are not exposed to CO in the environment, COHb levels are approximately 0.5%. This endogenous COHb comes from catabolism of hemoglobin and heme-containing enzymes of the liver. In comparison, COHb levels of cigarette smokers average about 4% and may reach up to 10% to 15%.[38] Frank CO poisoning, manifesting as headache, loss of motor control, and coma, generally occurs with COHb levels greater than 20%.

Individuals with cardiovascular disease are considered to be at the greatest risk from CO exposure. Standard exercise tests on subjects with ischemic heart disease have demonstrated a decreased time interval to the onset of angina at COHb levels ranging from 2% to 6%.[39] At COHb levels of 6%, patients with coronary artery disease have an increased incidence of arrhythmias.[40] These studies are relevant to the urban environment, where concentrations of ambient CO may be sufficient to cause blood COHb levels in this range. The 1-h 35-ppm and 8-h 9-ppm federal standards for outdoor air (Table 89-1) were selected to prevent COHb levels from rising above 1.5%, thereby protecting persons with coronary artery disease from aggravation of myocardial ischemia.

Panel studies of health individuals from the 2008 Beijing Olympics demonstrated a potential role of CO and other pollutants in inducing adverse changes in cardiorespiratory biomarkers. Due to government restrictions on emissions and traffic during the Olympic Games, levels of CO decreased 48% (together with similar-sized reductions in $PM_{2.5}$, SO_2, NO_2, and other pollutants) from pre-Game concentrations. These pollutant changes were associated with significant reductions in inflammatory and coagulation biomarkers as a proxy of endothelial dysfunction and pulmonary and systemic oxidative stress.[41]

Pollutant Mixtures

Much of the health effects research in this chapter are distilled down to the effects of individual pollutants. While it may be possible to isolate specific components, such as O_3, in a laboratory or controlled human inhalation study, this is an artificial distinction. Real-world exposures consist of a heterogeneous mixture of gases, liquids, and solid aerosols; for example, power plants release particles, NO_x, and sulfur oxides, and vehicle exhaust contains CO, NO_x, particles, and hydrocarbons. Many of these components may interact to synergistically augment or counteract pathophysiologic mechanisms of disease.

One alternative to characterizing pollutant health effects by individual component is to characterize health effects by pollutant source. Two pollutant sources that have received increased attention are traffic-related air pollution (TRAP) and wildfire smoke.

Traffic-Related Air Pollution Traffic is a major global source of pollution, with a significant portion of the population living less than 500 m (considered to be in close proximity) from a major roadway. Many of those who live further from these major arterials still spend a significant amount of time in vehicles as part of their daily routines, engaging in activities such as commuting. In the United States, the average adult spends approximately 55 minutes per day in traffic.[42]

The complex emissions from motor vehicles, broadly referred to as TRAP, include large quantities of CO_2, CO, hydrocarbons, NO_x, PM, and mobile-source air toxins, such as benzene, formaldehyde, and 1,3-butadiene.[43] Studies often look either at single traffic-related pollutants (most commonly NO_2 or elemental black carbon [BC]), or at residential distance to the nearest road as a surrogate for exposure to TRAP. Panel studies of commuters have also used extensive in-vehicle and on-road exposure monitoring to capture the emission profile.

Epidemiologic studies have shown an association between acute TRAP exposure, on the scale of 30 min to several hours, and increased risk of myocardial infarction or ventricular arrhythmia. Repeated health measurements demonstrate an increase in endothelial and cardiovascular biomarkers.[44–46] Individual pollutants measured as markers of traffic pollution have repeatedly been associated with both cardiovascular and respiratory events, and also with adverse changes in these biomarkers of mechanisms thought to underlie the cardiorespiratory response to pollution. While evidence clearly suggests that TRAP has adverse health effects, there is concern that coincidental exposures, such as stress and road noise, may confound these associations.

Both as a component and as a model of TRAP used in controlled inhalational exposures, diesel exhaust particles (DEP) have also been extensively studied. Diesel exhaust is an irritant to which some people are highly sensitive. It has been classified as a human carcinogen by the International Agency for Research on Cancer (IARC) based on the elevated risk for lung cancer.[47]

Wildfire Smoke Over the past decades, the world has seen an increase in the severity and frequency of wildfires. The most significantly affected areas cover a broad range of topography from boreal forests in Canada, Russia, and China; savannah grasslands in Africa; tropical rainforests including Brazil, Indonesia, and Nigeria; and temperate forests in the United States and Europe. Large forest fires are five times more frequent in the western United States than they were 50 years ago.[48] As traffic- and urban-related pollutants levels have decreased in response to regulations, wildfire smoke contributes to a larger portion of overall emissions. For example, wildfires in the United States contributed to more than 50% of estimated methane emissions and 20% of all fine particulate matter in 2012.[49]

This increase in wildfires is due to a combination of factors with large contributions from climate change, historic fire suppression policies, and a rise in population density near fire-prone areas—known as the human–wildfire interface. As temperatures rise, droughts intensify and the annual snowpack decreases, leading to drier forests that are more susceptible to burning. Historic forest management has caused an unnatural accumulation of understory trees and woody debris that provide fuel for wildfires. By one estimate, anthropogenic contributions to climate change account for approximately half of the increase in fuel aridity and have doubled the forest fire activity in the western United States.[50]

Wildfire smoke is a byproduct of combustion, principally composed of water vapor, CO_2, CO, and methane. Smoke also contains PM, VOCs, NO_x, hydrocarbons, trace metals, and thousands of other chemicals. The exact constituents are unique to the burn site—dependent on the type of vegetation, whether any buildings or synthetic material are consumed, and flame intensity. During the flaming stage of combustion, there is rapid release of CO_2 and H_2O, while smoldering fires cause incomplete combustion with dirtier emissions. As the plume disperses there is photochemical aging and formation of secondary pollutants, such as O_3. Smoke plume distribution and duration are affected by meteorologic conditions, including the ambient temperature, wind speed, and local topography. Wildfire smoke can traverse large distances, affecting communities that are located thousands of miles away from the source. For instance in 2015, Maryland had a large spike in O_3 caused by a wildfire that was burning in Canada.[51]

Levels of pollution observed during wildfire smoke events can reach staggering concentrations that can be sustained for days. Many of the gases and particles in smoke can act as mucosal and epithelial irritants, resulting in headache, sinus congestion, eye irritation, pharyngitis, and cough. Much of the morbidity and mortality due to wildfire smoke exposure is thought to be caused by ultrafine and fine PM, which precipitates a similar cascade of oxidative damage and inflammation as has been observed with other sources of ambient PM.

There is consistent epidemiologic evidence of an association between wildfire smoke exposure and acute respiratory outcomes, specifically emergency department visits and hospitalizations for respiratory infections, COPD, and asthma exacerbations. There is a mixed but growing body of literature demonstrating an association between acute exposures and cardiovascular outcomes, such as MI, arrhythmia, and acute coronary syndrome.[52] Most of the studies to date have focused on the effects immediately following a smoke event, but the chronic impact of repetitive, high exposures over multiple years remains unknown.

Inferred from knowledge about ambient air pollution, it is likely that chronic exposures to wildfire smoke will have a significant impact on overall morbidity and mortality. This presumption has been echoed in some early studies that examine the delayed impacts of smoke exposure. In wildland firefighters, there is a small decline in lung function that persists after the wildfire season.[52] A recent study in Montana also demonstrated an increase in influenza severity and mortality following a season with high wildfire smoke exposure.[53]

Toxic Air Pollutants

Approximately 200 “hazardous pollutants” are listed as air toxins in the 1990 Clean Air Act amendments. These substances include a wide variety of volatile organic compounds, pesticides, herbicides, and radionucleotides that are known to cause serious health effects in humans. For example, formaldehyde, a VOC that is commonly found in indoor and outdoor air, causes nasopharyngeal and lung cancer, irritation of the respiratory tree, and asthma exacerbations. Polycyclic organic matter (POM), a broad range of compounds that are byproducts of combustion and commonly found in diesel exhaust, also are known carcinogens. Importantly, approximately 1500 new chemicals are introduced into commerce each year.[54] Many of these substances have not undergone sufficient toxicologic assessment to determine whether they pose potential health risks and should be further regulated.

INDOOR AIR POLLUTION

Indoor environments are contaminated by numerous air pollutants, including those that have penetrated from the outdoor air and those generated from indoor sources. This section reviews exposures and health effects of the principal indoor pollutants. Similar to outdoor air pollution, indoor air pollutants typically occur as exposures to mixtures, rather than as single agents.

Overview: Sources and Classification of Indoor Air Pollution

There are many sources of indoor air pollution, including building materials and furnishings, appliances, household products, heating and cooling systems, excessive moisture, biologic agents, secondhand smoke, and outdoor sources (Table 89-4). Outdoor air can enter buildings by infiltrating through cracks or other leaky structures, natural ventilation through windows and doors, or mechanical ventilation systems. The amount of infiltration depends on the building type, insulation, window-opening behavior, weatherproofing, and climate conditions. In low- and some middle-income countries, the major source of indoor pollutants, often referred to as household air pollution (HAP), is incomplete combustion from biomass (plant or animal products) or coal fuels for heating and cooking.

The concentration of an indoor contaminant depends on the strength of its source, the rate of removal, the volume of the space, and the rate of air exchange between the space and outdoors. This *mass–balance* formulation indicates that the concentration of a contaminant can be reduced by limiting emissions from the source, increasing removal rate, or increasing exchange between indoor and outdoor air. In the typical modern building, the exchange of indoor with outdoor air is accomplished by a central heating, ventilating, and air-conditioning (HVAC) system. These systems are diverse, although all have the same purpose: the delivery of air of acceptable

TABLE 89-4 Sources of Common Indoor Air Contaminants

Exposure Category	Common Sources	Specific Exposures
Combustion byproducts	Biomass burning Gas stoves and appliances Propane engines Fireplaces/wood-burning stoves	Carbon monoxide Nitrogen dioxide Sulfur dioxide Particulate soot Nitrogenated compounds
Tobacco products	Cigarettes Pipes Cigars E-cigarettes	Particulate matter Carbon monoxide Nitrogen dioxide Carbon dioxide Hydrogen cyanide Nitrosamines Aromatic hydrocarbons
Building Material and Furnishing	Asbestos-containing insulation and fire-retardant material Furniture and paneling made of pressed wood Glues and resins Coating and cleaning agents Carpeting	Asbestos Volatile organic compounds, such as formaldehyde, benzene, terpenes
Outdoor sources	Infiltration of outdoor air Soil vapor intrusion Well water	Outdoor air pollution Pesticides Radon gas and progeny
Biologic organisms	Water-damaged surfaces Humidifiers with stagnant water Condensing coils and drip pans in HVAC system Animal dander Dust mites	Fungal spores Molds and mycotoxins Bacteria and endotoxins Virus Pollens Arthropods Allergens

quality to building occupants.[55] The volume of air to be delivered follows the recommendation of standards set by the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE).

Indoor air quality is a qualitative metric of contaminants in indoor air that can affect the occupant's health, comfort, and sense of well-being. Insufficient ventilation can lead to a perception of poor air quality and an increase in respiratory symptoms. As a by-product of respiration, CO_2 is a marker of the balance between the generation from building occupants and the removal through ventilation system and serves as a proxy for fresh-air ventilation in office buildings. In general, when indoor CO_2 concentrations exceed 1000 ppm, occupants have complaints indicative of insufficient ventilation.[56] Relative temperature and humidity also effect indoor air quality and individual perceptions of comfort. Temperatures over 71.6 to 73.4°F (22–23°C) are associated with mucosal irritation and fatigue, particularly during the colder season. Dry air is also associated with mucosal, ocular, and skin symptoms, while excess humidity can promote mold and dust mite growth. OSHA recommends that humidity be controlled between 30% and 60%.[57]

■ Indoor Air Pollutants: Exposures and Health Effects

Below we consider a variety of indoor air pollutants, including those derived from indoor combustion, organic compounds, radon, asbestos, artificial fibers, and biologic agents.

Indoor Combustion

Principle sources of pollutants related to indoor combustion include household air pollution, gas and wood-burning stoves, secondhand smoke, and aerosols from e-cigarettes.

Household Air Pollution Household air pollution (HAP) refers to emissions from the incomplete combustion of biomass burning from plant or animal products, and solid fuels such as coal or charcoal. Approximately one-third of the global population uses biomass burning or solid fuels for cooking, cleaning, and/or lighting. Women, young children, and infants are the most heavily exposed due to traditional gender roles, with women performing most of the cooking duties while often caring for children inside the home.[58] In addition to being the major source of indoor air pollution for a significant portion of the globe, HAP also is also responsible for approximately 14% of ambient air pollution and for approximately 3.5 to 4 million deaths per year.[6]

The sources of biomass fuel and pollutant by-products vary widely according to geographic area, local culture, and socioeconomic status. For example, coal is the primary source of fuel in China, while wood and charcoal are more heavily used in much of Africa, and animal dung is the major source available in rural communities or those at high altitude, such as Nepal.[58] Many of the hazardous components of HAP are similar to traffic-related pollutants and include PM, CO, SO_2, PAH, and endotoxins. In contrast to the PM from wildfire smoke, larger particles may be more important in HAP due to the high proportion of absorbed endotoxins. The emissions from these fuels are often smoky and reach high concentrations, with PM levels up to 1000 $\mu g/m^3$, due to use in poorly ventilated indoor areas with inefficient chimneys.[59]

The proposed pathophysiology of HAP is comparable to that of ambient air pollution with epithelial injury, oxidative stress, and local and systemic inflammation. In vitro and animal studies demonstrate that exposure to HAP is associated with airway hyperresponsiveness, decreased lung function, and altered immunity. The greatest increase in mortality from exposure to HAP is due to childhood PNA. HAP is also associated with increased incidence and severity of other respiratory infections, chronic lung disease and respiratory cancers. Epidemiologic studies indicate that early life exposures may lead to increased predisposition to develop asthma. There is growing evidence that HAP may also be linked with cardiovascular outcomes.

Exposure to HAP can be reduced through the introduction of improved fuels, cookstoves, heaters, and ventilation. Pellet fuels, liquid fuel such as propane, liquified petroleum gas (LPG), and biofuel are more efficient, and solar stoves can nearly eliminate emissions. The RESPIRE trial, which randomized families in Guatemala to improved chimney stoves versus traditional stoves, demonstrated a significant decrease in childhood pneumonia in the intervention group.[60] Despite these promising findings, other studies in low- and middle-income countries have more mixed findings. One explanation for the lack of clear health benefits in these epidemiologic studies is that the adoption of improved, new, efficient technology is challenging due to cultural and economic sustainability. Even in areas where national programs or research studies have introduced improved cookstoves and heaters, "stacking" often occurs, where traditional stoves are used concurrently with improved cookstoves.

While exposure to HAP may be somewhat reduced, it is unclear how much emissions need to be lowered to effectively decrease the risk of adverse effects.[61]

Gas and Wood-burning Stoves As opposed to HAP in low and middle-income countries, the major sources of indoor combustion byproducts in developed countries are gas cooking stoves, unvented space heaters, wood stoves, and tobacco smoke. Although vented to the outside by building codes, gas furnaces and water heaters may pollute residences because of flue gas spillage and back-drafting caused by improper installation, maintenance, device malfunction/wear, and weather conditions.

CO, a by-product of fuel combustion, is released indoors by cooking appliances, home heating systems, portable generators, and space heaters. Surveys of residential indoor concentrations have demonstrated that CO levels are typically low (2–4 ppm), even in the winter when windows are often closed and homes heated.[37] However, levels can increase precipitously in buildings with faulty, unvented, or improperly ventilated combustion sources. There are approximately 15,000 emergency department visits and 500 accidental deaths annually due to CO asphyxiation, with approximately 20% of the nonfatal cases attributable to malfunctioning heating appliances.[62]

In addition to CO emissions, gas cooking stoves can result in brief but high levels of exposure to NO_2, reaching up to 1000 ppb while the stove is in use. A number of epidemiologic studies have compared the occurrence of respiratory outcomes in children in homes having gas stoves to those living in homes with electric stoves. There is limited evidence that suggests gas cooking stoves are associated with increased respiratory infections, worsening of asthma symptoms, and decreased lung function.[63–65] Findings of these studies have been inconsistent, largely because of the methodologic complexities of investigating this association.

The use of wood for residential heating has become more prevalent in developed countries due to increasing energy prices and an emphasis on renewable fuels. Interestingly, in developed countries, studies of community wood smoke exposure have demonstrated more consistent evidence of adverse respiratory effects than studies of individual household wood smoke exposure.[66] While this may be attributable to study design with different exposure metrics, data suggest that the routine operation of a properly installed, maintained, and vented wood stove does not greatly affect indoor air quality. However, vented smoke may significantly affect ambient air quality and infiltrate neighboring homes. During cold periods in the winter, when there are more frequent stagnant air masses and temperature inversions, outdoor wood smoke particulate matter concentrations may remain elevated for extended time-periods. This impact on outdoor air quality may be responsible for the health effects demonstrated in studies of community wood smoke exposure.

Secondhand Smoke and E-cigarette Aerosol While the prevalence of smoking in the United States has decreased among adults to 13.7% in 2018, exposure to tobacco smoke remains common in public places and homes.[67] Additionally there is concern regarding the emergence and growing use of novel inhalation products, such as electronic cigarettes. The aerosols created from these electronic devices generally are at lower concentrations than traditional tobacco products but still contain many of the same air contaminants.

Secondhand smoke (SHS) refers to the combination of mainstream smoke exhaled by the smoker and sidestream smoke, released from the burning tobacco product end. Survey and biomarkers data on SHS exposure for nonsmokers and children have documented steady decreases over time. Among nonsmoking participants in the National Health and Nutrition Examination Survey (NHANES), measurable blood levels of cotinine, the nicotine biomarker, dropped from 87.9% in 1988 to 1991 down to 25.3% in 2011 to 2012.[68]

Hundreds of chemical compounds have been identified in cigarette smoke, but the indicators most often used to quantify its presence in the environment are total suspended PM, $PM_{2.5}$, CO, and nicotine.[69] Concentrations of PM measured over 24 h are generally two or more times higher in homes with active smokers compared to nonsmoking households. Nicotine is present as a gas in SHS and is a highly specific marker for tobacco smoke, with no other sources in indoor air. Several biomarkers of nicotine and tobacco specific carcinogens can also be measured in the blood, urine, saliva, and hair. As with other indoor air pollutants, SHS and e-cigarette aerosol exposure vary considerably depending on the number of active smokers, use patterns, size of room, and proximity to smoker.

The adverse effects of SHS have been assessed in the context of the voluminous evidence on active smoking and health, as well as detailed characterizations of the composition and toxicology of mainstream and sidestream cigarette smoke. Numerous studies have demonstrated that SHS is associated with a variety of malignant and nonmalignant diseases in nonsmokers. Household smoking, particularly maternal smoking, is associated with increased risk of lower respiratory tract infections, middle ear effusions and infections, chronic respiratory symptoms, and reduced lung function in children. Children with asthma whose parents smoke have heightened airway responsiveness and increased morbidity, as documented by indexes of medical care utilization. Exposure to SHS is also a suspected cause of asthma, and infants of smoking parents have increased airway responsiveness shortly after birth.[69]

Exposure to SHS was first linked with lung cancer in never-smokers in two reports published in 1981.[70] Subsequent epidemiologic studies have replicated these findings, demonstrating a consistent positive association between living with a smoker and the risk of lung cancer. The risk of lung cancer is increased by approximately 20% for never-smoking women married to smokers. Based on epidemiologic and toxicologic evidence, SHS is classified as a group I carcinogen, a designation applied to agents causally linked to cancer.[71]

There is also robust evidence supporting an association between SHS exposure and cardiovascular disease, particularly acute coronary syndrome. A number of epidemiologic studies demonstrate that marriage to a smoker increases the risk for ischemic heart disease.[69] SHS causes an estimated 23,000 and 70,000 cardiovascular disease–related deaths annually. A Cochrane review of the health impact of legislative smoking bans across multiple countries shows that the accompanying reduction in SHS is associated with improved CVD outcomes and a decrease in hospital admission for ACS.[72]

"Thirdhand smoke" refers to surface-deposited components (e.g., on clothing, furniture, and other surfaces) of tobacco smoke and metabolic by-products of these components.[73] Thirdhand smoke is neither smoke nor a pollutant present in the air; rather, it is composed of various compounds, many that are volatile or semivolatile, that may have a long-lived presence following deposition. Experimental research and field specimens show that these compounds may be long lived and undergo chemical transformations. Thirdhand smoke components may be absorbed via the skin or through ingestion of components on the hands or on contaminated objects that young children put into their mouths.

Organic Compounds

Organic compounds are ubiquitous indoors, where they are released from furnishings and equipment, construction materials, and consumer and office products.[74] The organic compounds found in indoor air can be grouped by boiling point range as volatile (0–240°C), semivolatile (240–380°C), and particulate (>380°C). The volatile and semivolatile organic compounds are most relevant to human health. VOCs exist as vapors over the normal range of air temperatures and pressures, whereas semivolatile organic compounds are liquids or solids but also evaporate.

Indoor concentrations of organic compounds are typically the main determinants of personal exposure, even in areas in close proximity to outdoor point sources. For example, while benzene is a byproduct of gasoline, oil refineries and chemical plants, the main contribution to personal exposure is either mainstream cigarette smoke or passive SHS.[75]

Formaldehyde is one of the most common VOCs, found in a variety of household products, paints and varnishes, preservatives, fertilizers, and wood products. The largest use of formaldehyde is in preparation of urea and phenol-formaldehyde resins, used to bind laminated wood products and particleboard. These products are widely used as shelving, counters, cabinets, and floor and wall coverings in buildings. Formaldehyde can act as a sensitizer and cause of immune-mediated asthma, as well as a potent mucosal irritant with ocular, airway, and neurologic effects. Formaldehyde is classified as a group I carcinogen by IARC and is associated with nasopharyngeal cancer and leukemia.[76]

The health risks associated with organic compounds are diverse and include carcinogens and mutagens (e.g., benzene), irritants (e.g., formaldehyde, terpenes), and neurotoxins (e.g., aromatic compounds). Despite these potential adverse effects, the exposure-disease associations are often poorly characterized due to the difficulty in characterizing indoor air exposures.

Radon

Radon is a naturally occurring, radioactive gas that is odorless and ubiquitous in the environment. Radon-222 and its parent, radium-226, are the decay products of uranium-238 and undergo further disintegration through a series of short-lived progeny. Alpha particles, beta particles, and gamma rays are released during each stage of decay until the formation of a stable atom of lead. Irradiation of respiratory epithelial cells by alpha particles damages cellular DNA and can cause lung cancer.[77]

The principal source of radon in buildings is naturally occurring gas in soil, that seeps in through openings in sump pump wells, drains, utility access holes, or other cracks.[78] The driving pressure for entry of soil gas into a building is the pressure gradient established by a structure across the soil. In most locales, building materials and water used in the home do not contribute significantly to concentrations of radon indoors.

Extensive data on radon concentrations in homes in the United States show that the average value is about 1.5 picocuries per liter (pCi/L).[79] Homes with high concentrations have been identified in all states, although the proportion exceeding the EPA's action guideline of 4 pCi/L is heterogeneous and varies with local geology. In a national survey conducted from 1988 to 1991, the EPA measured radon concentration in 6000 randomly selected homes in the United States. About 6% of homes were estimated to exceed the guideline of 4 pCi/L annual average.[80]

The risks associated with residential exposure to radon are extrapolated from studies in underground workers, in particular uranium miners, who are exposed to the highest concentrations of radon.[81] These studies consistently show an association between radon exposure and lung cancer, with a synergistic effect due to cigarette smoking. Pooled case-control studies from residential exposures confirm that these lower-dose exposures are still associated with lung cancer. Current risk models assume a linear dose-response with no threshold, implying that values under current guidelines cause a significant number of lung cancer cases. Based on these models, radon is considered to be the most common environmental cause of lung cancer after tobacco smoke, and may be responsible for approximately 12% of lung cancer deaths in the United States.[82]

The substantial lung cancer burden attributed to indoor radon has led to programs for reduction of exposure. The program in the United States, conducted by the EPA, calls for voluntary measurement of radon levels in single-family homes and mitigation if the annual concentration exceeds the agency's guideline level of 4 pCi/L.[83] Simple measures, such as sealing basement cracks and sump holes, can be effective at lowering radon levels. Other approaches include ventilating the basement to the outside and, for homes built on concrete slabs, by providing a system to exhaust the soil gas from beneath the slab. In areas that have high background levels of radon, "radon-resistant" construction techniques are used as a preventative measure.

Asbestos and Artificial Fibers

Asbestos (Chapter 85) is a group of naturally occurring inorganic fibers that are resistant to heat and corrosion, leading to its extensive use in building products in the 1900s. Due to recognition of asbestos-related health effects, its use was banned in the 1970s. Many buildings, however, still have asbestos-containing materials in thermal and acoustic insulation, fire protection, and reinforcement of building products. Despite the frequent presence of large amounts of asbestos in buildings, indoor exposure occurs only when fibers are aerosolized through disturbance of friable asbestos building materials.

Air monitoring shows extremely low average asbestos concentrations under the conditions of normal building use.[84] There is little concern that building occupants could develop asbestosis or other diseases that require high cumulative exposures, although there may be elevated risks for conditions where there is no safe threshold of exposure, such as mesothelioma or lung cancer. In addition, custodial and maintenance workers could be exposed to higher levels of asbestos in their cleaning duties, re-suspending settled dust from friable building materials. Several studies have shown that custodial and maintenance workers may have increased risk of developing pleural plaques and possibly asbestosis.

Biologic Agents

The indoor biologic agents include a variety of allergens and microbes, including bacteria, molds, pollen, animal dander or urine, cockroach feces, and mites. Levels may increase through the accumulation of materials indoors (such as human and animal dander), or by growth (such as fungi and bacteria on interior surfaces or in air-conditioning systems). Other biologic agents, such as pollen and fungal spores, enter the indoor environment predominantly via outdoor sources: through air infiltration, or as inadvertent travelers on people, animals, or objects.

The growth of microorganisms on interior surfaces causes some of the most prevalent and severe problems due to indoor biologic pollution. Any substrate that can provide a source of both carbon and water can support the growth of microorganisms, including leaks from water pipes and roofs, prior floods, and condensation in rooms with high relative humidity (>70%). Humidifiers, vaporizers, and air conditioners also can become contaminated and distribute fungal fragments, spores, and dissolved allergens into room air.

Fungi are present in the air of virtually all indoor environments and can be detected by visual inspection or odor. Commonly isolated genera include *Cladosporium*, *Penicillium*, *Alternaria*, *Epicoccum*, *Aspergillus*, and *Drechslera.* Molds and other fungi may adversely affect human health through allergy, infection, or immunologic reactions. Mycotoxins, naturally occurring secondary metabolites produced by certain fungal species, also are associated with a range of biologic effects, including some acute poisonings. The mycotoxins produced by *Stachybotrys chartarum*, also known as black mold, have been popularized as a cause of "idiopathic pulmonary hemorrhage" and remains a controversial topic in the scientific community. Recent critical reviews of the literature have concluded that indoor airborne levels of microorganisms are only weakly correlated with human disease or building-related symptoms—and that a causal relationship has not been established between these complaints and indoor exposures to *S. chartarum*.[85]

The presence of dampness and mold, determined by questionnaire, has been associated with upper respiratory symptoms and eye irritation in large cohort studies of children. These associations persist after adjustment for known determinants of respiratory symptoms, including maternal smoking, city, child's age and sex, and parent education. Similar findings have been reported in adults, and a systematic review concluded that dampness in buildings contributes to adverse health effects in persons with and without atopy.[86] The evidence on dampness was reviewed by an Institute of Medicine committee, which did not find the evidence to be sufficient to conclude that dampness causes respiratory symptoms or asthma.[87] While it seems likely that the mechanism underlying the effects of dampness is via microbiological growth and subsequent evolution of allergenic or toxic agents, the current literature is inconclusive and does not clearly implicate any agents.

Specific allergens of concern include those of dust mites (*Dermatophagoides pteronyssinus*, *Dermatophagoides farinae*, and *Euroglyphus maynei*), pests such as cockroaches and mice, and domestic animals, such as cats and dogs. Levels of antigen can often persist in indoor environments for long periods, even after the source is gone.[88] Airborne and dust concentrations of allergens probably have limited value for assessing the contribution of a particular allergen in causing disease. Levels of allergens and other microbial particles are highly variable and affected by activities such as vacuuming, sweeping, dusting, making beds, scrubbing contaminated surfaces, and using electric fans. Factors such as aerodynamic behavior, respirability, solubility, and cross-reactivity with other allergens are also important in the process of immunologic sensitization and the development of allergic disease.[89]

Biologic agents in indoor air may cause disease through various mechanisms, including direct toxicity, infections, and immune hyperresponsiveness. A complete review of these diverse effects is beyond the scope of this chapter, but selected elements are addressed briefly in the section below.

■ Clinical Syndromes Associated with Indoor Environments

During the last 20 years, complaints attributable to indoor environments have generally been classified into one of two broad groups: specific building-related illnesses and sick building syndrome (SBS).

Building-related illnesses have a number of etiologies and pathophysiologic mechanisms, but the specific agent responsible for causing the disease is present in the indoor environment. Examples include hypersensitivity pneumonitis caused by fungi in the ventilation system, and Legionnaires' disease resulting from transmission of the organism that grows in cooling tower water. Building-related allergic respiratory disease and epidemic asthma have been reported in office buildings in association with air-handling systems and humidifiers contaminated with bacteria and fungi.

SBS refers to nonspecific health problems related to indoor air quality, often in nonindustrial buildings where known toxic exposures would be considered atypical. From a medical perspective, these problems often do not constitute easily recognized diagnoses and are more notable due to the clustering of nonspecific symptoms in relationship to one location. Irritation of mucosal surfaces and neurotoxic effects may contribute to the nonspecific symptom complex that often includes headache, fatigue, and difficulty concentrating. Atopic individuals have been shown to have lower irritant thresholds than non-atopics. Multiple factors, including specific exposures, inadequate ventilation, and poor building maintenance have been linked to SBS. Panel studies in Denmark have found that complaints were most often attributed to the ventilation system, SHS, office machines, and other sources.[90]

Building-related symptoms that occur in the context of the workplace may be particularly challenging. The healthcare provider needs to establish the connection between the workplace and the occurrence of symptoms and then seek a solution that includes identifying and remediating the responsible factors in the workplace. The investigation requires sufficient awareness of the possible causal role of the indoor environment, as well as the potential contribution of psychosocial, organizational, or labor-management issues. Resolution may require an evaluation and intervention by indoor air quality professionals, but extensive and expensive exposure assessment is frequently unrevealing. The physician evaluating an individual patient in these situations may be unable to resolve the patient's symptoms without recognizing the underlying problems. Guidance for the clinician has been offered by the ATS.[91,92]

SUSCEPTIBLE POPULATIONS

Exposure to air pollution is ubiquitous. To fully understand the health consequences of exposure, it is important to recognize the disproportionate variation in risk among different populations, both at the individual and community level. Susceptibility refers to the intrinsic factors that can alter risk, such as life stage, ethnicity, sex, underlying health status, and genotype. Vulnerability is the term used to describe the external factors that can increase the potential for exposure to air pollution, such as outdoor laborers or communities that live next to point sources of pollution. Susceptibility and vulnerability factors are often intertwined, further compounding risk. For instance, low socioeconomic status is often associated with higher exposure to air pollution, diminished baseline health, and lack of resources to mitigate adverse effects.[93] The confluence of susceptibility and vulnerability factors that lead to a disproportionate impact of air pollution on populations of lower socioeconomic status is usually framed as "environmental justice" and often has roots in historic segregation or structural racism.

The legislative history of the Clean Air Act mandated that the primary NAAQS were to be set low enough to protect the health of all susceptible groups within the population except those requiring life-support systems. While only asthma and emphysema were specifically identified as susceptible populations in the Clean Air Act, recent epidemiologic evidence suggests that additional populations need to be considered, including persons with pre-existing coronary artery disease, those with other chronic lung diseases, infants and fetuses, and the elderly.

In this section, we consider the evidence concerning these susceptible groups (Table 89-5). Pulmonologists are likely to be asked about the consequences of pollution exposures by persons with chronic lung diseases. Patients may report being adversely affected by exposures and may request guidance concerning control measures—for example, purchase of an air-cleaning device or additional medication use when exposed.

■ Clinical Studies in Susceptible Populations

Epidemiologic studies provide much of the evidence on the acute effects of pollutants in susceptible populations. There have also been several controlled laboratory studies of volunteers with preexisting disease, such as asthma or coronary artery disease, which have attempted to identify specific effects of individual pollutants in susceptible groups.

A large body of evidence demonstrates that individuals with COPD and asthma are at high risk of exacerbations from air pollution, as determined by respiratory symptoms, medication use, urgent care visits, and hospitalizations. Recent studies have focused on groups with other underlying chronic lung disease. These have

TABLE 89-5 Populations Considered Susceptible to Air Pollution

Population	Potential Mechanism	Consequences
Persons with chronic lung disease Asthma COPD Cystic fibrosis Interstitial lung disease Post–lung transplant	Increased airway responsiveness Increased pulmonary and systemic inflammation Impaired respiratory defenses Reduced level of lung function	Increased risk for exacerbation and respiratory symptoms Increased lung function decline Increased mortality
Persons with coronary heart disease	Impaired myocardial oxygenation	Increased risk for myocardial ischemia
Cigarette smokers	Impaired defense and clearance, lung injury	Increased damage through synergism
Elderly	Impaired respiratory defenses Reduced functional reserve	Increased risk for respiratory infection Increased risk for clinically significant effects on function
Infants and fetuses	Immature defense mechanisms of the lung	Increased risk for respiratory infection Increased incidence of asthma

demonstrated that pollution is associated with an increased risk of exacerbations in individuals with cystic fibrosis and non-CF-related bronchiectasis,[94] faster progression and exacerbations in patients with idiopathic pulmonary fibrosis,[95,96] and higher odds of developing chronic lung allograft dysfunction in persons who are post–lung transplant.[97]

Persons with coronary heart disease also have been identified as a group at risk from increased levels of air pollution. Studies conducted at relatively low COHb levels demonstrate significant effects of CO exposure on exercise capacity, the occurrence of myocardial ischemia, and ventricular ectopy. Controlled exposure studies have also shown that acute exposure to diesel exhaust results in exercise-induced ST-segment depression in individuals with stable coronary artery disease.[98]

Individuals at the extremes of age may also be at a heightened susceptibility to the effects of air pollution. Cells may be particularly sensitive to the oxidative damage caused by pollutants during certain stages of growth and development, leading to alterations in organogenesis, immune system development, and epigenetic programming with long-ranging consequences. Increasingly, studies have linked gestational exposures to an increased risk of childhood asthma, low birth weight and poor fetal growth, and neurodevelopmental delay.[99–101] On the other end of the spectrum, older individuals also have been classified as particularly sensitive to the health effects of pollution exposure. The mechanisms for this heightened susceptibility are incompletely understood, but may be, in part, attributable to weakened defense mechanisms, existing comorbid conditions, diminished reserves, and higher cumulative exposures.[102,103]

Several studies have attempted to understand genetic susceptibility to pollutant effects. While these investigations primarily are useful to inform a mechanistic basis for these effects, studies have examined whether several genetic polymorphisms either protect or give an individual increased susceptibility to these cardiorespiratory health effects. For example, individuals without a polymorphism to protect against oxidative stress (e.g., glutathione S-transferase mu 1 [GSTM1] null) may be more responsive to air pollution health effects than individuals with wild type GSTM1.[104] Similarly, variants in nociceptive receptors, such as TRPV1, seem to affect the subsequent vascular response to air pollutants.[105] More work is needed, however, before we understand whether genetic markers of susceptibility have a role in improving prevention of pollutant-related health effects.

In summary, existing respiratory and cardiovascular conditions may make a patient susceptible to air pollution–mediated health effects, as several mechanisms thought to be involved in mediating a cardiovascular health response to air pollution may already be activated.

■ Control Strategies

Efforts to mitigate the health effects of indoor and outdoor air pollution requires a multipronged approach, with strategies aimed at the population level and individual guidance. While emission reduction and improvement in air quality is the ultimate goal, personal strategies to diminish the risk of adverse effects are particularly important in susceptible individuals or during high-pollution events. Clinicians should be familiar with practical recommendations and guidance to individuals that can minimize the effects of air pollution. Clinicians may serve as consultants or as advocates in seeking to reduce the effects of indoor and outdoor air pollutants through population-oriented control approaches.

Community-oriented Strategies

Government policies aimed at emissions reduction through regulations and laws are some of the most effective mechanisms used to achieve lasting improvements in air quality. Since the passage of the Clean Air Act amendment in 1970, there has been approximately a 70% reduction in the aggregate emissions of the six criteria air pollutants across the United States, despite a growing population and economy.[106] Similarly, climate change policy directed toward limiting CO_2 and greenhouse gas emissions has the co-benefit of reducing fossil fuel consumption and the production of toxic air pollutants. The promotion of alternative energy sources, clean vehicles with improved fuel efficiencies, and green building techniques not only can improve the trajectory of a warming climate, but also has the immediate benefit of cleaner air.[107]

On a more local scale, redesigning land use can be an effective conjunctive measure to mitigate the public health effects of air pollution exposure.[93] Traditional urban design places densely populated areas and key community resources near major traffic arteries with the highest levels of traffic-related air pollution. Intentional urban design of infrastructure can promote physical separation of sensitive populations from mobile and point sources of pollution. For example, the California Air Resources Board made formal distance recommendations for building healthcare facilities, schools, day cares, and residences away from freeways, rail yards, and other pollution sources.[108] While such forward-thinking urban design strategies are not yet the standard, they have significant potential to reduce exposures in the most vulnerable populations.

TABLE 89-6 Air Quality Index and Activity Recommendations

Index Values	Levels of Health Concern	Cautionary Statement
0–50	Good	None
51–100	Moderate	Unusually sensitive people should consider reducing prolonged or heavy exertion outdoors
101–150	Unhealthy for sensitive groups	Active children and adults, and people with lung or heart disease, should reduce prolonged or heavy exertion outdoors
151–200	Unhealthy	Active children and adults, and people with lung or heart disease, should avoid prolonged or heavy exertion outdoors; everyone else should reduce prolonged or heavy exertion outdoors
201–300	Very unhealthy	Active children and adults, and people with lung or heart disease, should avoid all outdoor exertion; everyone else should avoid prolonged or heavy exertion outdoors
301–500	Hazardous	Everyone should avoid all physical exertion outdoors

Data from Air Quality Index (AQI): A Guide to Air Quality and Your Health. Triangle Park, NC: U.S. Environmental Protection Agency Office of Air Quality Planning and Standards Outreach and Information Division Research; 2014. EPA-456/F-14-002.

While changes in regulations and community infrastructure are instrumental for long-term air pollution mitigation, governmental and environmental agencies also play an important role in monitoring and public reporting of air quality. Pollution forecasting websites, such as Air Now, can be used to track the level of pollution on a fine spatial and temporal scale. The Air Quality Index (AQI) (Table 89-6) is communication tool used by governmental agencies to illustrate current pollutant levels based on national air quality standards. The AQI is color coded into six categories indicating increasing levels of health concern, with a level below 50 indicating good air quality and level over 300 corresponding to hazardous air quality. Users should be aware that the AQI is an imperfect tool, that people frequently confuse AQI levels with pollutant concentrations, that the AQI attempts to provide guidance about the pollutant of most concern on a particular day, and that different countries set their own levels of concern and their own language regarding guidance—a level that is "unhealthy" in one country may be considered acceptable in another.

Patient-oriented Strategies

Where levels of pollution exceed standards, individual actions to reduce person-level exposure may be beneficial. Potential interventions to reduce personal-level exposure to air pollution can be categorized as behavioral, technologic, physical, and pharmaceutical (Table 89-7). While there is a paucity of studies investigating the effectiveness of clinical strategies based on the AQI, behavioral modifications aimed at limiting time-activity patterns in areas with high pollution are considered to be the most effective strategy.[109] These could include reducing exercise in urban areas, selecting travel routes that minimize near-road exposure, or staying indoors during periods with high pollution concentrations. In general, concentrations of ambient pollutants are lower indoors, and the EPA advises the public to remain inside during periods of high air pollution to reduce the risk of acute health effects. It is important to qualify this recommendation, as the infiltration rate can vary widely depending on building structure, weather conditions, and the ventilation system. Additional actions, such as closing all windows and recirculating the indoor air through existing HVAC systems, may further reduce the infiltration of ambient pollutants.[110]

Technologic solutions for reducing personal exposure to pollution include the use of portable or central air cleaning systems. High Efficiency Particulate Air (HEPA) filters mechanically remove greater than 99.9% of particles with a diameter of 0.3 μm from filtered air. Studies have shown that HEPA filtration can reduce indoor $PM_{2.5}$ concentration between 40% and 70%, and it may have associated mortality benefits during high-pollution events, such as

TABLE 89-7 Personal Strategies to Mitigate Effects of Air Pollution Exposure

Intervention	Examples	Comments
Monitor local air forecast	• Automated air pollution networks that provide warnings (e.g., AirNow) • Personal pollution monitors	• May be particularly helpful for susceptible populations
Activity modification to reduce exposure to pollutants	• Stay indoors during high pollutant events • Reduce exercise in areas with high pollutants • Select transportation routes to avoid high pollutant zones	• Consider variable infiltration of outdoor pollutants into buildings • Trade-off between health benefits of physical exercise and adverse health effects of pollution
Clean indoor air	• Portable air filters, such as HEPA air purifiers • Central air cleaning systems	• Must be appropriately sized for room • Filters must be maintained • Can be expensive
Personal protective equipment	• Negative-pressure air-purifying respirators (APR), such as N95 • Positive-pressure APR	• Must have correct filter • Negative-pressure APR must have appropriate seal/fit to be effective • May be uncomfortable or difficult for individuals with chronic cardiopulmonary disease to wear
Medications or dietary supplements	• Antioxidants, omega 3-fatty acids, targeted therapy to proposed pathophysiology	• Mixed evidence of benefit, not currently recommended

wildfire smoke exposure.[111] To be effective at exposure reduction, air purifiers should be placed in rooms where participants spend most of their time, and they need to be appropriately sized to the area of the space filtered. While HEPA filters capture particles on fibrous material, electrostatic air cleaners use electrostatic forces to capture particles and may produce harmful byproducts, such as ozone. Due to their potential to produce O_3, many agencies recommend against the routine use of ionizers and other electrostatic air cleaners. There is no role for O_3-based air cleaners in settings with human occupants.

The use of personal protective equipment, such as negative-pressure filtering face masks, to physically reduce pollutant exposure has been variably adopted by different countries. In some heavily polluted cities, such as Beijing, face masks are commonly used outdoors. Respiratory protective equipment has been developed for use in the workplace to minimize exposure to toxic gases and particles. However, the efficacy of respirator is dependent on the pollutant, filter material, respirator design, and user fit. Many of these devices, particularly those likely to be most effective, add to the work of breathing and may be poorly tolerated by persons with respiratory disease. Cloth and dust masks may be able to decrease large irritant particles from entering the nasopharynx but do little to reduce $PM_{2.5}$ and hazardous gases. Negative-pressure respirators, such as N95s (defined as masks able to reduce 95% of PM <0.3um), can effectively reduce the concentration of contaminants depending on the quality of the individual's face seal. While there is controversy whether widespread use of respiratory protection should be recommended, many guidelines advocate for use of an N95 or other tight-fitting respirator when exposure to high levels of ambient air pollution is unavoidable. Under most circumstances, healthcare providers should not suggest respiratory protection as a method for reducing the risks of ambient air pollution.

By targeting the proposed pathophysiologic mechanism, various medications have also been investigated as a means to block adverse pollutant effects. Overall, the results of these studies have been disappointing with negative or mixed results.[112] For example, some randomized control trials of antioxidant supplementation showed improvement in diesel exhaust–mediated health outcomes, while others showed null or even augmented responses.[105] Currently there is little compelling evidence to suggest that pharmaceutical or dietary interventions can help reduce the health risks associated with air pollution exposure.

Guidance to patients related to ambient particulate air pollution calls for tracking when pollution levels are high, by weather forecasts, EPA alerts, or visible haze and reduced visibility. At such times, it is reasonable to advise patients to reduce outdoor activity, particularly with exercise, and avoid locations where pollution levels may be particularly high, for example, adjacent to busy roadways. Such guidance is particularly appropriate for people susceptible to health effects of air pollution (e.g., people with asthma, COPD, coronary artery disease, and/or hypertension). Although mechanisms of toxicity are not completely understood, avoiding air pollution exposure can only help reduce air pollution-related cardiorespiratory morbidity and mortality.

Susceptible patients should be counseled concerning the nature and degree of their susceptibility. The use of medication should follow the usual clinical indications, and therapeutic regimens should not be adjusted because of the occurrence of a pollution episode without evidence of an adverse effect on symptoms or function. In the laboratory, inhalation of cromolyn sodium and bronchodilating agents blocks the response to some pollutants, but use of these drugs solely because of exposure to air pollution cannot be advised. Similarly, although there have been investigations of antioxidant agents in preventing some air pollutant effects, the evidence is not sufficient to conclude that these are safe and effective.

TABLE 89-8 Questions and Answers About Indoor Air Pollution

Question	Answer
Do air cleaners work?	There is increasing evidence that filter-based air purifiers are helpful, particularly for susceptible populations or during high pollution events. People should avoid ozone-generating air purifiers.
Should the radon concentration in my home be measured?	Yes, radon can be readily measured at relatively low cost, and mitigation is feasible.
Should the air ducts in my home be cleaned?	There is no evidence of health benefits for cleaning air ducts.
Will controlling mites be beneficial?	Controlling mite levels is beneficial for persons with mite-sensitive asthma.
Should my home be humidified?	Humidification may increase allergen levels.

Pulmonologists may be concerned with diverse issues related to the control of indoor air pollution, ranging from answering patients' questions about pollutant health effects and control, to management of complex problems in large buildings. Some commonly asked questions and answers that reasonably reflect the state of the evidence are provided in (Table 89-8). The clinically relevant microenvironments are numerous, including the home, the workplace, public buildings, and places where leisure time is spent.

CHAPTER 90

Acute and Chronic Responses to Toxic Inhalations

Austin J. Jolly
David A. Schwartz

INTRODUCTION

The lungs and airways are in constant contact with the outside world and are especially vulnerable to toxic substances present in the environment. Within seconds of exposure to an inhaled toxin, pathologic events occur that may cause immediate distress, produce illness lasting days, or even lead to the development of chronic lung disease. In this chapter we discuss the pathology and pathophysiology that can result from various inhaled toxins and highlight the role of several common and medically significant toxic inhalants that are known to cause acute and chronic pathophysiologic responses in the lung. We also describe several systemic syndromes caused by acute toxic inhalations. The scope of this chapter does not include chronic exposure to low levels of toxins.

DETERMINANTS AND MECHANISMS OF IRRITANT-INDUCED PULMONARY INJURY

Inhaled toxins exist in many forms and may be categorized by considering their physical properties. General categories include gases, vapors, fumes, aerosols, and smoke. A variety of factors determine the pathologic results of a toxic inhalation: the size of inhaled particles, the water solubility of the inhaled substance, the concentration of the inhalant in ambient air, the duration of exposure, the presence or absence of ventilation, and relevant host factors (age, smoking status, comorbid diseases, use of respiratory protection, and perhaps even genetic susceptibility). While toxic inhalants provoke a broad range of chemical and biologic activities that contribute to pathogenesis, their physical properties, namely, their particle size and water solubility, are of fundamental importance in determining the site and severity of pulmonary injury. Tables 90-1 to 90-3 and Fig. 90-1 summarize the physical properties of the discussed inhalants that substantially affect the resulting pathogenesis of these agents.

The size of aerosolized particles is of critical importance in inhaled toxin pathogenesis. In general, larger aerosolized particles are more likely to deposit on the nasopharynx via impaction and not gain access to the lower airways, while smaller particles are able to penetrate smaller airways and effect toxicity at the level of the alveolus. Aerosolized particles larger than 30–80 μm are not inhalable through the nose,[1] and particles larger than 5 μm typically do not reach the alveoli.[2] Ultrafine particles (those <0.1 μm) are able to remain airborne long enough to reach the alveoli where

TABLE 90-1 Definitions of Types of Inhaled Substances

Gas: a formless state of matter in which molecules move freely about and completely occupy the space of enclosure
Aerosol: a relatively stable suspension of liquid droplets or solid particles in a gaseous medium
Coarse particles: particles between 1 and 10 μm
Fine particles: particles between 0.1 and 1 μm
Ultrafine particles: particles less than 0.1 μm
Vapor: the gaseous form of a substance that normally exists as a liquid or solid and that generally can be changed back to a liquid or solid by either increasing ambient pressure or decreasing the temperature
Fume: an aerosol of solid particles generally less than 0.1 μm in size that arises from a chemical reaction or condensation of vapors, usually after volatilization from molten materials
Smoke: the volatilized gaseous and particulate products of combustion; particles generally less than 0.5 μm in size and do not settle readily

they can transcellularly diffuse across the alveolus–capillary interface or be retained in surfactant, evading mucociliary or immune cell–mediated clearance mechanisms.[3] Inhaled particles may have direct toxic effects themselves, or they may function as vehicles for adsorbed gaseous agents that are toxic to terminal bronchioles and alveolar cells.

In addition to particle size, the relative water solubility of an inhalant determines where along the respiratory tract toxicity will occur. Substances with high water solubility, such as ammonia, sulfur dioxide, and hydrochloric acid, provoke immediate and evident injury to the conjunctiva and mucosal surfaces of the upper airways; they are largely absorbed by mucus lining the pharynx and larynx and often react there to form caustic acids and alkalis. The provoked symptoms quickly prompt exposed individuals to flee the area or contain the source of exposure, reducing the duration of exposure. These compounds can also activate irritant receptors in the upper airways, provoking a bronchoconstrictor reflex that may further limit access of the inhalant to lower airways.[4] In contrast, compounds like phosgene and ozone have low water solubility and thus fail to cause immediate irritation, promoting longer exposure to the inhalant and deeper penetration of the lower airways. Compounds of intermediate solubility, for example, chlorine gas, typically have pathologic effects throughout the respiratory tract. These differences in solubility can be overcome by differences in concentration and duration of inhalant exposure: virtually any inhaled toxin (even the most soluble agents) can cause diffuse damage of the respiratory tract by overwhelming the absorptive capacity of the upper respiratory tract. Furthermore, adsorption of a toxic gas on particulate matter may permit a toxin access to otherwise unreachable airways.

Host factors also play a significant role in predicting an individual's response to a toxic inhalation. Underlying pulmonary or extrapulmonary disease may worsen a patient's response to an exposure. Children deposit a smaller fraction of inhaled particles in their nasopharynx than adults and thus may be at elevated risk of lower airway exposure and pathology.[5] Moreover, as some gases (such as chlorine and sulfur dioxide) are heavier than air and stay closer to the ground, children may be subjected to a longer duration and higher concentration of gas than adults near the same site of toxin release. With particles greater than 0.5 µm, breathing through one's nose increases upper airway particle deposition compared to mouth-breathing; this difference is absent with particles smaller than 0.5 µm.[6] Tobacco smoking impairs ciliary clearance and cellular defense, limiting the exposed patient's ability to clear inhaled particles and prolonging exposure. Patients with increased minute ventilation (such as those panicking at the scene of an irritant gas release) are at elevated risk of increased exposure and toxicity. Experiments with inbred strains of mice suggest that genetic variants may alter the risk of responding to various inhaled toxins.[7] For example, investigators exposed a panel of 43 genetically diverse mouse strains to phosgene gas to induce acute lung injury followed by genome-wide association studies (GWAS) using a high-density single nucleotide polymorphism assembly. These findings revealed candidate genes such as *Alox5* (involved in leukotriene production) and *Itga9* (linked to TGF-β signaling) are associated with increased susceptibility to toxin-induced acute lung injury in mice.[8]

Injury from toxic inhalation may occur via several mechanisms. If the concentration of the inhalant is high enough and if ventilation is inadequate, simple asphyxiation due to displacement of atmospheric oxygen may occur. The reflex bronchoconstriction triggered by upper-airway irritant receptor activation may itself cause inadequate oxygen inhalation. Cell injury from acute toxin exposure typically occurs via nonimmunologic mechanisms of injury and inflammation, generally via formation of an acid (chlorine, oxides of nitrogen, phosgene, and sulfur dioxide), an alkali (ammonia), or reactive oxygen or nitrogen species (ozone, oxides of nitrogen and chlorine). Acid formation results in coagulative necrosis of underlying tissue, while alkali exposure causes a liquefaction of mucosa and characteristically deep lesions within the respiratory epithelial tissue. Reactive oxygen and nitrogen species and their derivatives achieve local tissue damage via lipid peroxidation and protein oxidation, which can compromise the integrity of cell membranes leading to cytotoxicity.[9] Free radicals may be direct derivatives of inhaled substances, or they may be released by alveolar macrophages that are activated by inhalant exposure.[10] All three types of tissue damage generally lead to an increase in expression of proinflammatory cytokines that can perpetuate the acute injury and may be responsible for the development of later sequelae. Disruption and repair of injured airway epithelial tissue may compromise host defenses against further infectious or irritant substances. A role played by the innate immune system in disease progression is evident in the case of endotoxin exposure in organic dust toxin syndrome (ODTS, below), and may be a host factor in the response to ozone and nitrogen dioxide.[7,11]

PATHOGENESIS AND CLINICAL PRESENTATION OF TOXIC INHALATION INJURY

Mechanisms of disease and clinical manifestations based on respiratory site exposure are considered below.

Upper Airway

Effects of toxins on the upper airways are typically sudden and short-lived compared to those more distal along the respiratory tract; chronic pathology in this region is unusual. Compounds that provoke a response in the nose, pharynx, and larynx tend to be particulates with relatively large average particle size or gases with high water solubility. Acids, alkalis, and reactive oxygen and nitrogen species may all cause tissue injury in this region depending on the inhaled compound and its reactions along airway epithelium. Characteristic tissue injury depends on dosage and ranges from slight edema of the nasopharynx and larynx to epithelial ulceration and frank hemorrhage. Once the airway epithelia are compromised, it fails to function as a protective barrier against the environment. Underlying inflammatory cells, nerves, muscles, and blood vessels become exposed, which may exacerbate the inflammatory response. The nasopharynx contains abundant vascular beds underlying the mucosa, and these vascular beds are highly responsive to neurohumoral stimuli. Due to their sensitivity, these vascular beds are largely responsible for toxin-induced upper airway constrictive reflexes that can compromise patency of the airway.[12] An obstructive response to some irritants starts to occur at concentrations only barely perceivable as irritating.[13] Irritant exposure to the upper airway can affect nonrespiratory structures such as the eustachian tube leading to otitis media.[12]

The typical presentation of patients with acute exposure of irritant substances to the upper airways includes burning sensations of the nasal passages and throat, copious sputum production, coughing, and sneezing. Extrapulmonary manifestations include burning of the eyes, profuse lacrimation, headache, and dizziness. The most serious risk in the exposed patient is airway obstruction due to reflex bronchospasm or laryngospasm, mucosal edema, increased secretions, and sloughed epithelial cells. Patients presenting with hoarseness or stridor should be carefully observed for further evidence of airway compromise. Although inhalational injury confined to the upper airways tends to be self-limited with no or few long-term sequelae, a chronic rhinitis following irritant exposure, *reactive upper airway dysfunction syndrome* (RUDS), has been described[14] and was observed among World Trade Center rescue workers following the attacks of September 11, 2001.[15] Similarly, it has been reported that workers exposed to irritants or organic dusts can develop a chronic rhinitis termed *occupational rhinitis* characterized by persistent sneezing, itching, and rhinorrhea.[16]

Patients with acute toxic exposure to the upper airways should be immediately removed from the source, which may require removal of the patient's clothes. The patient's airway should be secured and monitored; racemic epinephrine may be used for bronchodilation, but it should not delay endotracheal intubation if necessary. Frequent suction may be required. Profuse amounts of water should be irrigated over exposed surfaces. Supplemental oxygen should be provided if appropriate. Patients with extensive upper airway edema may benefit from corticosteroids,[17] but this is unsupported by clinical trials. Ophthalmologic pathology such as conjunctivitis can develop after exposure; consultation should be sought for management of eye complications.[18]

Conducting Airways

Acute or chronic effects on the airways may be observed.

Acute Injury

As is the case with the upper airways, the conducting airways protect their submucosal structures with epithelium that may be compromised by acute inhalational injury. The resulting edema, inflammation, and bronchoconstriction may be life-threatening if it results in an obstructed airway, and without its epithelial barrier the airway is vulnerable to infections and other environmental pathologies. This damage to the epithelium appears to occur at the tight junction interface between cells,[19–21] resulting in increased epithelial permeability to other irritants, which gain direct access to effector cells within the subepithelial mucosa. Resulting bronchospasm may cause ventilation–perfusion mismatch.[22] The smooth muscle of the airways can be hyperresponsive in the hours and days following irritant exposure, an effect probably mediated by the neutrophilic and eosinophilic inflammatory response inhalational injury provokes.[23,24]

Conducting airway injury may manifest as intrathoracic airflow obstruction hours after the initial insult. Patients with histories of exposure who present with any evidence of respiratory compromise should be hospitalized for observation, even if asymptomatic. Findings of concern include expiratory wheezing, decreased airflow on peak expiratory flow measurement or spirometry, abnormalities of gas exchange, or an abnormal chest x-ray. Likewise, patients with complaints of dyspnea or chest tightness should be observed carefully and treated symptomatically with inhaled steroids and bronchodilators, even in the absence of objective findings. When significant airflow obstruction is present, systemic steroids may be of some utility.

Chronic Injury

Two forms of chronic injury include reactive airways dysfunction syndrome and vocal cord dysfunction.

Reactive Airways Dysfunction Syndrome

A persistent asthma-like disease following acute exposure to an irritant inhalant, known as *reactive airways dysfunction syndrome* (RADS, or "Brooks syndrome") was named in 1985 based on a cohort of 10 previously healthy individuals who developed chronic asthma-like symptoms after acute exposure to gases and fumes; all 10 patients demonstrated a positive methacholine challenge suggesting hyperreactive airways.[25] These findings were previously observed among World War I soldiers exposed to war gases.[26] Investigation and diagnosis of the disease is generally limited by the absence of spirometry results in patients prior to exposure and any notable confounding factors (e.g., cigarette smoking), but numerous reports exist of previously asymptomatic patients experiencing hyperreactive airway disease presenting soon after a single toxic exposure and persisting for months or years.[25,27–34] RADS is distinguished from immunologic occupational asthma because it directly follows an acute, single exposure with a minimal-to-nonexistent latency period after inhalation of the offending substance.[35]

The pathogenesis of RADS likely begins with the initial injury to and desquamation of the epithelium exposing underlying nervous and vascular tissue resulting in hemorrhage and edema. Neurogenic inflammation from exposed nerve endings is likely involved. Long-term structural remodeling of the airways culminates in epithelial regeneration and fibrosis resulting in chronic changes in the tissue.[36–38] Airway narrowing may be due to mucosal edema, inflammation, or structural changes to the architecture of the bronchial wall.[39]

RADS typically presents abruptly within 24 hours following exposure with the classic symptoms of obstructive airway disease: wheezing, chest tightness, dyspnea, and cough. The symptoms and obstructive findings on exam and spirometry are relieved by bronchodilators, although not as effectively as in other types of reactive airway disease (perhaps due to chronic fibrotic remodeling of the conducting airways). The disease can persist for months and may, in some instances, be permanent.[40] A recent case report shows that a patient with severe unremitting symptoms of RADS for 5 years following an ammonia exposure responded to high-dose oral vitamin D supplements.[41] These findings were consistent with a more recent case report describing a patient who was acutely exposed to high levels of ammonia during a spill and developed severe symptoms of RADS that affected the patient's quality of life leaving the patient virtually housebound for 5 years. Aggressive vitamin D supplementation was initiated; when serum levels of vitamin D reached 200 nmol/L the patient's symptoms resolved.[35] Anecdotally, inhaled corticosteroids have shown benefit in relieving airflow obstruction.[36] Systemic corticosteroids have been proven beneficial in an animal model of RADS.[42]

Vocal Cord Dysfunction

Vocal cord dysfunction may also follow a single acute irritant exposure and may be confused with RADS.[43,44] The disorder may be caused by reflex response to nerve stimulation by irritants.[45] Patients suspected of having RADS who do not respond appropriately to bronchodilators should be evaluated for vocal cord dysfunction; direct laryngoscopy is the gold standard of diagnosis.[44]

■ Lower Airways and Pulmonary Parenchyma

While the upper and conducting airways are certainly at risk for inhalant exposure, the lower airways and lung parenchyma are primary sites for inhalational injury. Effects may be acute or chronic.

Acute Injury

Although all toxic inhalants are capable of producing distal airway disease at extreme concentrations and durations, the gases most likely to do so are those with low water solubility like phosgene and nitrogen dioxide, which bypass reflex bronchoconstriction and absorption by upper airway mucous (Fig. 90-2). The initial pathologic events in distal airways are caused by direct cellular toxicity of an inhaled agent and its derivatives, which compromise the alveolar–capillary interface.[46] Some of this cytotoxicity may be derived indirectly from reactive oxygen species released from activated inflammatory cells.[10] In the absence of an intact alveolar–capillary interface, profound pulmonary edema may develop that impairs gas exchange and can prove fatal. The severity of this pulmonary edema, which typically presents after a latent period of several hours following the initial insult, is likely dose related. This process may cause no more than slight dyspnea and cough with a mild alveolar infiltrate, or it may progress via diffuse alveolar damage to adult respiratory distress syndrome (ARDS).[47] For this reason, patients with exposure to gases capable of causing distal airway disease should be hospitalized and monitored for symptoms of respiratory distress and with serial chest x-rays for at least 24 hours following exposure. Development of ARDS from toxin exposure likely shares a common pathway with other causes of acute lung injury, and management is similar: supportive care with mechanical ventilation at lower tidal volumes,[48] careful control of blood glucose, surveillance for infection, and deep vein thrombosis prophylaxis. Diuresis, IV corticosteroids, prone positioning, nitric oxide inhalation, and exogenous surfactant are all unsupported by clinical trials but potentially confer some benefit.[49] Diffuse bronchiolitis also has been reported following acute exposure.[50]

Chronic Injury

Two forms of chronic injury include bronchiolitis obliterans and cryptogenic organizing pneumonia.

Bronchiolitis Obliterans Bronchiolitis obliterans (BO) is a well-documented but infrequent long-term sequela of toxic gas exposure, especially of nitrogen dioxide,[51,52] but also to ammonia,[53] mercury,[54] and sulfur dioxide.[55,56] BO is an inflammatory-mediated obstructive lung pathology of the smallest airways characterized by injured epithelium and excessive fibroproliferation.[57] Histopathologically, the involved tissue may show peribronchiolar smooth-muscle cell hypertrophy, inflammatory infiltrates surrounding the terminal bronchioles, and bronchiolar fibrosis.[58] The disease typically presents 1 to 3 weeks following the initial lung injury and pulmonary edema (Fig. 90-3). The interim is often free of symptoms. When BO does develop, patients may present with dyspnea on exertion or obstructive findings on spirometry. Physical exam may be either unremarkable or remarkable only for early inspiratory crackles. Chest x-ray will either be normal or demonstrate hyperinflation. Pulmonary function tests typically demonstrate airflow obstruction that may in some cases also be associated with restrictive defects. On biopsy, granulation tissue will be seen in the lumen of small airways and bronchiole walls may be obliterated by fibrous scarring. Corticosteroids may be of benefit in preventing or alleviating BO if administered early in the course of the disease,[59] although this is controversial.

Cryptogenic Organizing Pneumonia Cryptogenic organizing pneumonia, COP (formerly known as bronchiolitis obliterans organizing pneumonia, BOOP), is another observed delayed sequela of toxic inhalation.[60,61] COP is a form of interstitial lung disease with alveolar invasion of inflammatory cell infiltrates followed bFGF-mediated organization of fibroblasts leading to pulmonary fibrosis.[62] *Masson bodies* are the term given to accumulating intraluminal granulation tissue that can be visualized by H&E stain. Although not reproduced in other case studies, there has been a report of a previously healthy 20-year-old male who developed COP after acute exposure to a jalapeño grease fire.[63] Capsaicin and other jalapeño-derived compounds are known causes of bronchiolar inflammation and epithelial mucosal damage, but this case marks one of the first accounts of the development of COP from these specific inhalants. This example expands on what is currently known about inhalant exposure and COP and emphasizes the value of taking a comprehensive exposure history in patients with lung injury of unknown etiology.[63] Patients with inhalant-induced COP present in the weeks following exposure with fever, a persistent and nonproductive cough, sore throat, and malaise. Late inspiratory crackles may be observed. Chest x-ray may reveal bilateral patchy "ground-glass" densities that start as focal lesions but may coalesce with time. Pulmonary function tests generally reveal a restrictive process with decreased diffusion capacity. COP responds well to corticosteroids,[64] although a small number of patients may develop progressive fibrosis. Duration of therapy should be guided by the patient's clinical status.

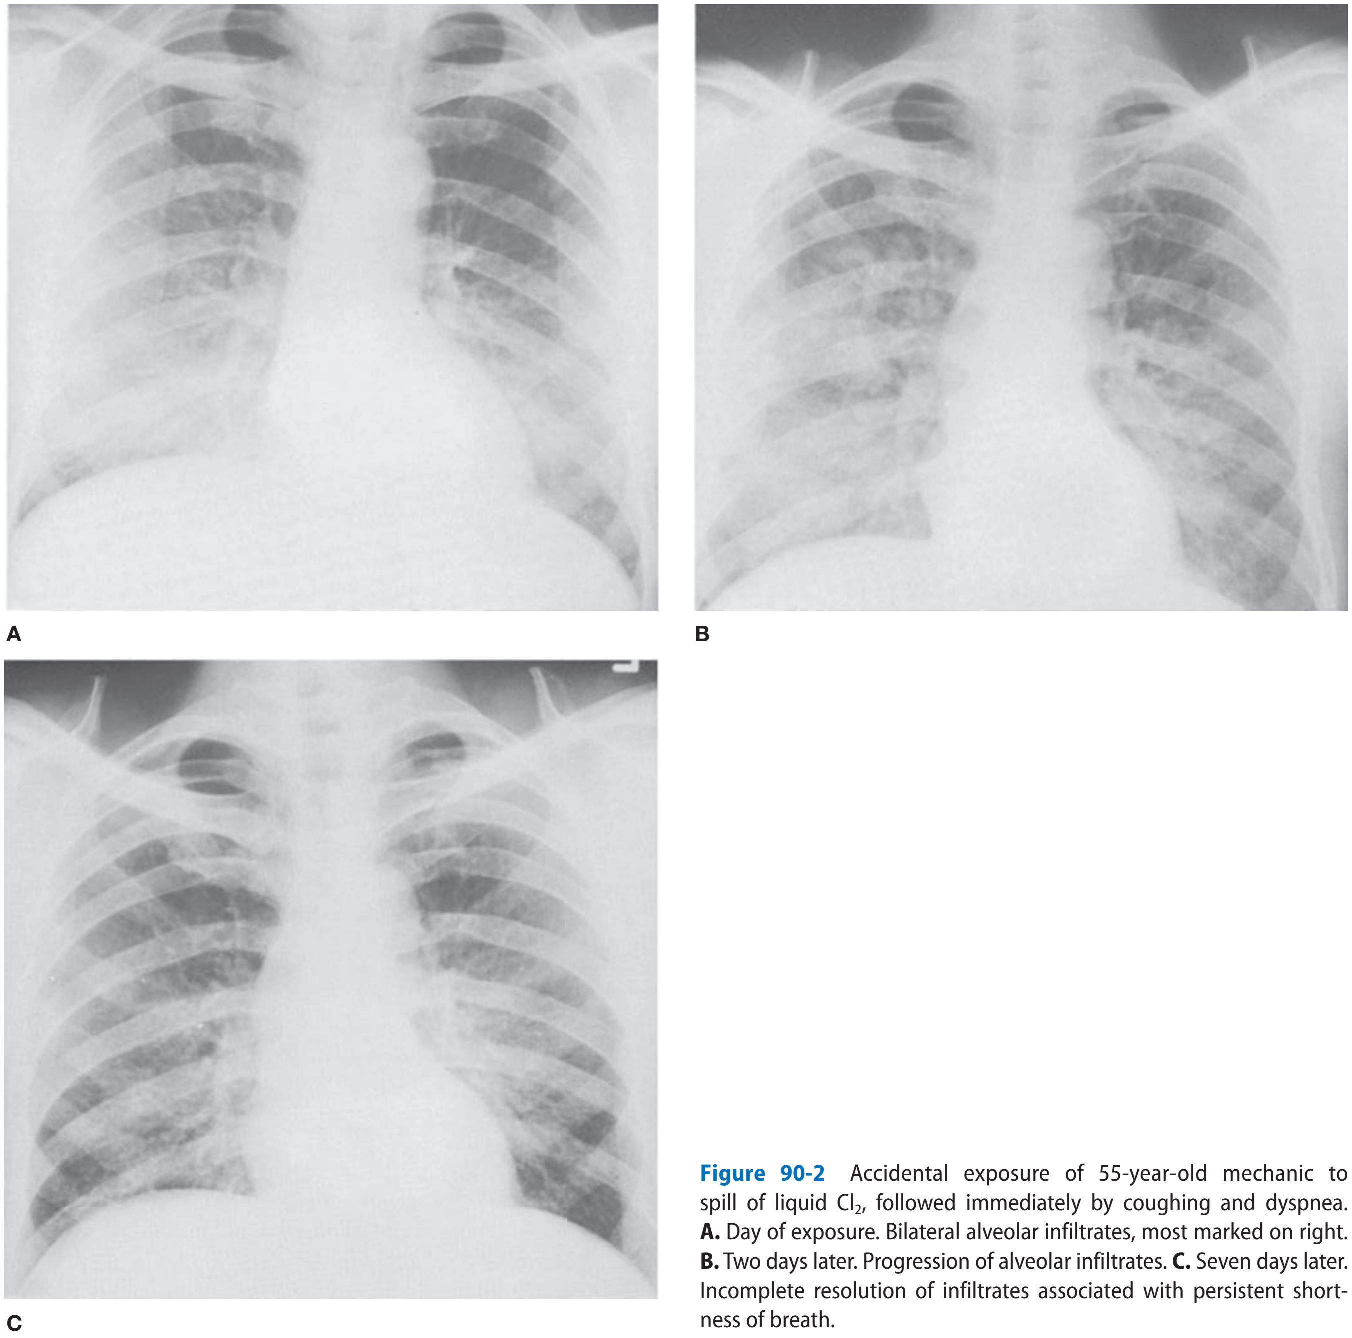

Figure 90-2 Accidental exposure of 55-year-old mechanic to spill of liquid Cl_2, followed immediately by coughing and dyspnea. **A.** Day of exposure. Bilateral alveolar infiltrates, most marked on right. **B.** Two days later. Progression of alveolar infiltrates. **C.** Seven days later. Incomplete resolution of infiltrates associated with persistent shortness of breath.

EFFECTS OF SPECIFIC INHALED TOXINS ON THE RESPIRATORY SYSTEM

The respiratory consequences of inhalation of commonly encountered toxins are discussed individually below.

■ Ammonia

Anhydrous ammonia (NH_3) is a stable colorless gas at room temperature. Ammonia is a hygroscopic nitrogen-containing compound typically dissolved in water at 5% to 10% (weight:volume) concentration for household cleaning products or upward of 25% concentration for commercial products,[65] making ammonia rank among the most commonly spilled hazardous substances (Table 90-4).[66] Familiar to all as a household cleaner, it also has countless uses in industry: as a chemical coolant used for refrigeration, as a fertilizer, as a fixative in photocopiers and in the manufacture of polymers and explosives. Small amounts are naturally present in the atmosphere as products of the putrefaction of vegetable and animal proteins. The pungent, suffocating smell of concentrated ammonia (as low as 5 ppm) is immediately recognizable. Due to the prevalence of ammonia in household cleaners and to its use in smelling salts (which exploit the noxious effect of ammonia on nasal membranes to arouse consciousness), the odor threshold may extend to over 50 ppm because of the olfactory fatigue and adaption.[67,68] Ammonia is frequently dissolved into water for storage and transportation and vaporizes readily on exposure to air. Most inhalation exposures are the result of accidental releases, including tank leaks and transportation mishaps,[69–71] and most exposures occur in the industrial workplace.[72] A reported source of exposure is via fumes produced in clandestine methamphetamine laboratories.[73] A more recent example from 2019 highlights how ammonia exposure can affect public health at a community-level. In Beach Park, a suburb of Chicago, an agriculture tractor was towing 2-ton containers that were leaking ammonia. A gas cloud quickly covered

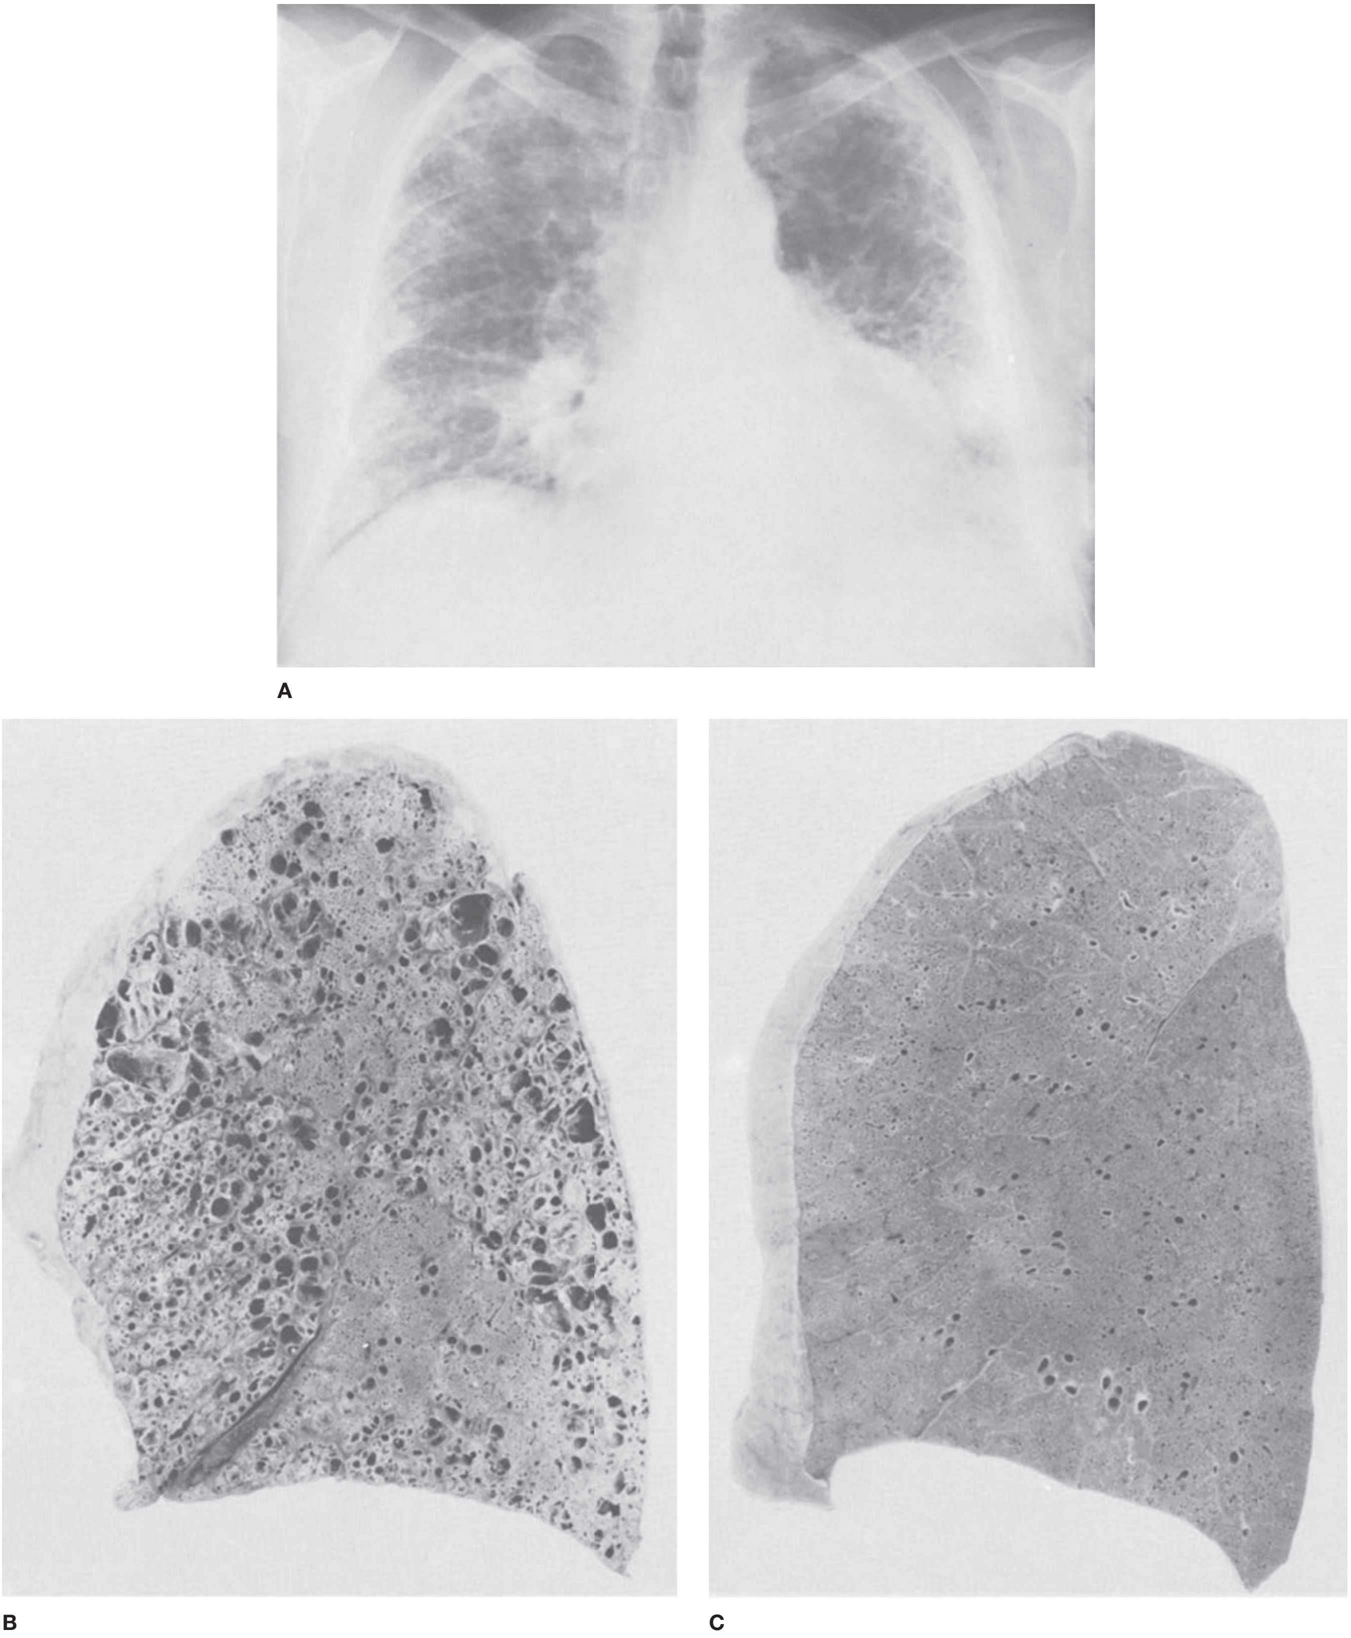

Figure 90-3 Bronchiolitis obliterans in a 63-year-old man who had been exposed to a wide variety of unidentified fumes in his jobs, which included welding. **A.** Chest radiograph. Diffuse pulmonary fibrosis and honeycombing, most marked in the peripheral portions of the lungs. **B.** Sagittal section of lung from same patient showing markedly dilated airspaces. Microscopic sections revealed bronchiolitis obliterans and chronic interstitial pulmonary fibrosis. **C.** Normal lung from a 43-year-old man who died suddenly. The difference between B and C in the alveolar portions of the lungs is striking. *(Reproduced with permission from Dr. R. Ochs.)*

TABLE 90-4 Pulmonary Manifestations of Toxin Inhalation

		Acute Clinical Manifestations		Chronic Clinical Manifestations	
Substance	**Onset**	**Upper Airway Irritation**	**Pneumonitis, ARDS**	**Bronchiolitis Obliterans, BOOP**	**RADS**
Irritant gases					
Ammonia	Minutes	Severe	+	+	+
Chlorine	Minutes to hours	Moderate	+	−	+
Hydrogen chloride	Minutes	Severe	+	−	+
Oxides of nitrogen	Hours	Mild	+	+	+

the suburban area and lingered for several hours. Thirty-seven people were hospitalized, 7 of whom in critical condition.[74]

The mechanisms of toxicity to the respiratory system involve both direct irritation and alkaline chemical burns. Due to its hygroscopic nature, ammonia tends to affect the proximal airways, where it reacts rapidly with the water present on mucosal surfaces to form ammonium hydroxide, causing tissue liquefaction. This necrosis liberates formerly intracellular water, which serves as further reactant for ammonia, perpetuating the reaction. In addition to the alkali burns caused by the generated ammonium hydroxide, thermal burns can result from the heat generated by this exothermic reaction. The resulting injury, typical of alkali burns, penetrates deeply. The initial injury to the mucosa of the oropharynx can cause edema, hemorrhage, sloughing of tissue, and increased secretions that can bring about fatal upper airway obstruction. Ammonia is directly caustic to airways at concentrations of 1000 ppm and higher.

Although concentrated at the proximal airways, the effects of ammonia have been observed at all levels of the respiratory tract. The penetration of the gas to the smaller airways and alveoli is a function of its concentration and the duration of exposure. Reported acute conditions associated with ammonia exposure include pulmonary edema, laryngitis/tracheobronchitis, bronchiolitis, and bronchopneumonia; reported chronic sequelae include bronchiectasis, bronchospasm/asthma (termed *reactive airways dysfunction syndrome*), and chronic obstructive pulmonary disease.[75] There are several reports of interstitial lung disease following a single exposure to ammonia.[72] A biphasic pattern of pulmonary response to ammonia inhalation has been reported, characterized by initial, acute pneumonitis that may clear over the next 2 to 3 days, followed in some individuals by the gradual development of airway obstruction and respiratory failure.[69] There may be a correlation between the development of a bacterial superinfection after exposure with the ensuing emergence of bronchiectasis.[76] In one review of published case reports, 21% of patients with acute ammonia inhalation died within 60 days of exposure.[75] The most common causes of death were laryngeal edema and obstruction, noncardiogenic pulmonary edema, and extensive pneumonic complications.

Management of a patient who has experienced ammonia inhalation requires removing the patient from the source of the irritant, securing the airway, and immediately irrigating all exposed surfaces (especially the eyes) with copious amounts of water. Humidified oxygen should be administered early. Airway management aggressiveness depends on the extent of complications such as laryngeal edema, pulmonary edema, hemoptysis, or respiratory failure that occur.[77] Rales detected on physical exam are predictive of the subsequent hospital course, even in the absence of hypoxemia and chest x-ray abnormalities.[69] Medical management is largely supportive. Aerosolized bronchodilators together with corticosteroids can be administered to treat bronchospasm. Corticosteroids and antibiotics are both frequently used, but both are unproven in human trials.

■ Chlorine, Chloramines, and Hydrochloric Acid

Chlorine (Cl_2) is a greenish-yellow gas that is heavier than air and is a common gas of intermediate water solubility. Although it has a distinct bleach-like odor, patient exposure to it may be prolonged compared with other toxic gases due to its delayed and gradual irritation of mucosal surfaces and its high density, which keeps it low to the ground. The first reports of its toxicity followed its use as an agent of chemical warfare in World War I, and war gassings remain the largest historic source of chlorine gas exposure.[78] Most exposures since then have occurred in the industrial setting, where chlorine is used in the manufacture of paper, cloth, antiseptics, and other products.[79] More common in the household is the liberation of chloramines and other toxic chlorine derivatives from the reaction of chlorine-containing products (such as hypochlorite bleach) with ammonia or products containing hydrochloric or phosphoric acid. Numerous exposures to chlorine gas have occurred near swimming pools, where chlorine-releasing agents (e.g., calcium hypochlorite and chlorinated isocyanuric acids) are used in water purification.[50]

The pathogenicity of chlorine gas derives directly from elemental chlorine's effects on the respiratory tract and indirectly from its reaction with water to form hydrochloric acid (HCl) and hypochlorous acid (HOCl). The character and distribution of injury from chlorine exposure varies according to duration of exposure and the relative concentrations of elemental chlorine and its derivative compounds. HCl and HOCl possess considerable water solubility and are responsible for the tissue damage sustained by the upper airways and ocular conjunctivae. Irritation to trigeminal nerve endings caused by these compounds can cause a reflex bronchoconstriction that may contribute to compromise airway diameter.[80] In addition to causing the tissue coagulation typical of acid exposures (described above), these compounds ionize and enter cells, where they may form reactive oxygen species. HOCl has been shown to react with nitrite (NO_2^-) to produce reactive nitrogen-containing compounds able to nitrate, chlorinate, and dimerize phenolic amino acids.[81] As nitrite and nitric oxide (its parent compound) levels are elevated at sites of tissue inflammation, this potentially is another mechanism of injury.[82] Although lower respiratory tract irritation has been reported following high-level exposures, less than 5% of inhaled chlorine gas penetrates beyond the upper airways.[83] Fatal dosages from chlorine inhalation have ranged from 50 to 2000 ppm.[50]

The immediate clinical manifestations of acute chlorine exposure are typical of irritants of its solubility: rhinitis, cough, dyspnea, wheezing, and chest tightness, along with conjunctivitis and skin irritation.[84] When chlorine gas exposure has resulted acutely in death, autopsies have revealed diffuse ulcerative tracheobronchitis, pulmonary edema, thrombi within pulmonary vessels, and denudation of respiratory tract epithelium.[85] Acute respiratory symptoms are more prevalent and severe among patients who already have chronic respiratory disease. In 2005, a derailment train released 40 to 60 tons of chlorine gas near a small town in South Carolina. Nine people died and 71 were hospitalized. The majority of people (>90%) had respiratory symptoms including wheezing, rales/crackles, cough, decreased breathing sound, rhonchi, and labored breathing. Autopsy findings revealed the causes of death to include asphyxia, lactic acidosis, and acute respiratory failure.[86]

The lasting respiratory sequelae of chlorine gas exposure have been described since the years following use of the gas in World War I.[87] Reported long-term pulmonary diseases following exposure have included both restrictive and obstructive processes, frequently resolving to normal function within a month and almost always before 2 years following exposure. Reactive airways dysfunction syndrome may be an infrequent sequela of high-level exposures to chlorine.[27,88] Other chronic sequelae from chlorine exposure include airway hyperresponsiveness and epithelial remodeling. ARDS may develop if chlorine bypasses the proximal airways and reaches the lower lung fields, and it is estimated that there is up to 1% mortality in individuals with severe chlorine exposure.[89]

Patients who have been exposed to chlorine gas should be managed according to the severity of their presenting symptoms similarly to other victims of irritant inhalation. The treatment for lung injury is primarily supportive care including humidified oxygen administration, lung protective mechanical ventilation, and pharmacologic therapeutics. Nebulized sodium bicarbonate has shown promise as a useful treatment[90,91] but lacks supporting clinical trials and showed no outcome benefit in a relatively large observational study of chloramine gas exposure.[92] Beta-agonist bronchodilators and corticosteroids are frequently used and are probably of benefit. The reported benefit of corticosteroid administration is anecdotal[85] and unconfirmed by clinical trial.

■ Sulfur Dioxide

Sulfur dioxide is a heavy, colorless, and highly water-soluble gas that has the distinct, pungent odor of burnt matches. It is generated in the combustion of coal and petroleum and is often used as a preservative in alcoholic beverages and fruit. Industrial exposures have occurred around ore smelting, metal smelting, oil refining, sugar refining, and the bleaching of wool and wood pulp. In 1930, 63 people died and thousands became ill in the narrow Meuse River Valley of Belgium due to the trapped high concentrations of sulfur dioxide from the waste products of industry resources (United States Environmental Protection Agency). Sulfur dioxide is among the most harmful gases released to the atmosphere during volcanic eruptions;[93] in 1986 the gases emitted from Lake Nyos killed nearly 2000 people in Cameroon.[94] Sulfur dioxide's great density keeps it low to the ground and slow to dissipate from sites of release; thus, children may be at an increased risk of exposure.

Sulfur dioxide reacts with water present on mucus membranes to form sulfuric acid, which, like other acids, causes tissue coagulation underlying exposed surfaces. Sulfuric acid also further dissociates into hydrogen ions, sulfite, and bisulfite,[95] which can then react with oxygen to produce reactive oxygen species; ensuing lipid peroxidation may be a contributing mechanism of injury to immediate tissues and elsewhere.[9,96] In an animal model of chemical-induced lung injury, rats were exposed to a single dose of 2200 ppm sulfur dioxide and subject to analysis for acute and chronic respiratory responses to sulfur dioxide (Fig. 90-4). Five hours post-exposure revealed abundant macrophage and neutrophil airway infiltrates associated with epithelial damage. The rats demonstrated an exaggerated methacholine response 24 hours post-exposure, suggesting the development of hyperresponsive airways. Histopathologic analysis and molecular assays demonstrated collagen deposition and increased TGF-β signaling 14 days post-exposure.[97] These results suggest sulfur dioxide is sufficient to induce proinflammatory and profibrotic responses in the acute and chronic phases, respectively.

Sulfur dioxide is detectible to humans at 3 to 5 ppm and is lethal at levels exceeding 400 ppm for 1 minute.[98] High water solubility makes sulfur dioxide primarily an upper airway irritant. The direct irritant of bisulfate iron inhibits mucociliary transport.[99] The irritation-induced parasympathetic stimulation leads to smooth muscle contraction and mucosal secretion. Exposures of high enough intensity can irritate both upper and lower airways. Patients exposed typically present with dyspnea, burning of the nose and throat, rhinorrhea, cough, and airway obstruction.[100] Proximal airway injury is characterized by acute denudation of the airway mucosa without inflammatory cell infiltrates. When lower airways are exposed, alveoli fill with fluid due to noncardiogenic pulmonary edema and the clinical picture is consistent with ARDS. Alveolar architecture is generally preserved. Extremely high-intensity acute exposures can lead within minutes to death from respiratory failure due to a combination of alveolar hemorrhage and edema, possible reflex vagal stimulation, and the asphyxiating effect of high concentrations of sulfur dioxide.[101] Reactive airways dysfunction syndrome has been reported following single sulfur dioxide exposure;[34] bronchitis also has been observed.[102] One pattern of postexposure progression reported is a rapid recovery followed several weeks later by the onset of irreversible airflow obstruction due to bronchiolitis obliterans.[101] Care for patients who have been exposed to sulfur dioxide is supportive: humidified supplemental oxygen, bronchodilators, and intubation and ventilation if necessary. The use of corticosteroids in the setting of ARDS following sulfur dioxide exposure has not been shown to be of benefit, but a trial is not unreasonable. Antibiotics may be reserved for use upon evidence of infectious complications.

■ Nitrogen Oxides

Nitrogen oxides are ubiquitous air pollutants, released from automobile engines and the combustion of coal and petroleum and present in cigarette smoke. High-level acute exposure is most likely to occur in industrial settings, including mining, acetylene welding, and explosives manufacturing. A well-known form of exposure occurs in "Silo-filler's disease," in which farmers inhale concentrated nitrogen dioxide (NO_2) gas released within silos by decomposing nitrogenous biomaterial.[51,103] Exposures to high levels of nitrogen dioxide have been attributed to blast furnaces,[50] anesthetic gases,[104] military incidents,[105,106] and ice hockey arenas (secondary to combustion byproducts from ice-resurfacing machines).[107–110] Nitrogen dioxide is a liquid at room temperature and a reddish-brown gas above 70°F. The acrid smell of nitrogen dioxide makes the inhalation exposure to be avoided at low concentration. Thus, short term (1-hour peak) nitrogen dioxide concentration outdoor is unlikely to exceed 0.2 ppm.[111] However, low concentrations at 4 ppm may anesthetize the nose, resulting in overexposure.

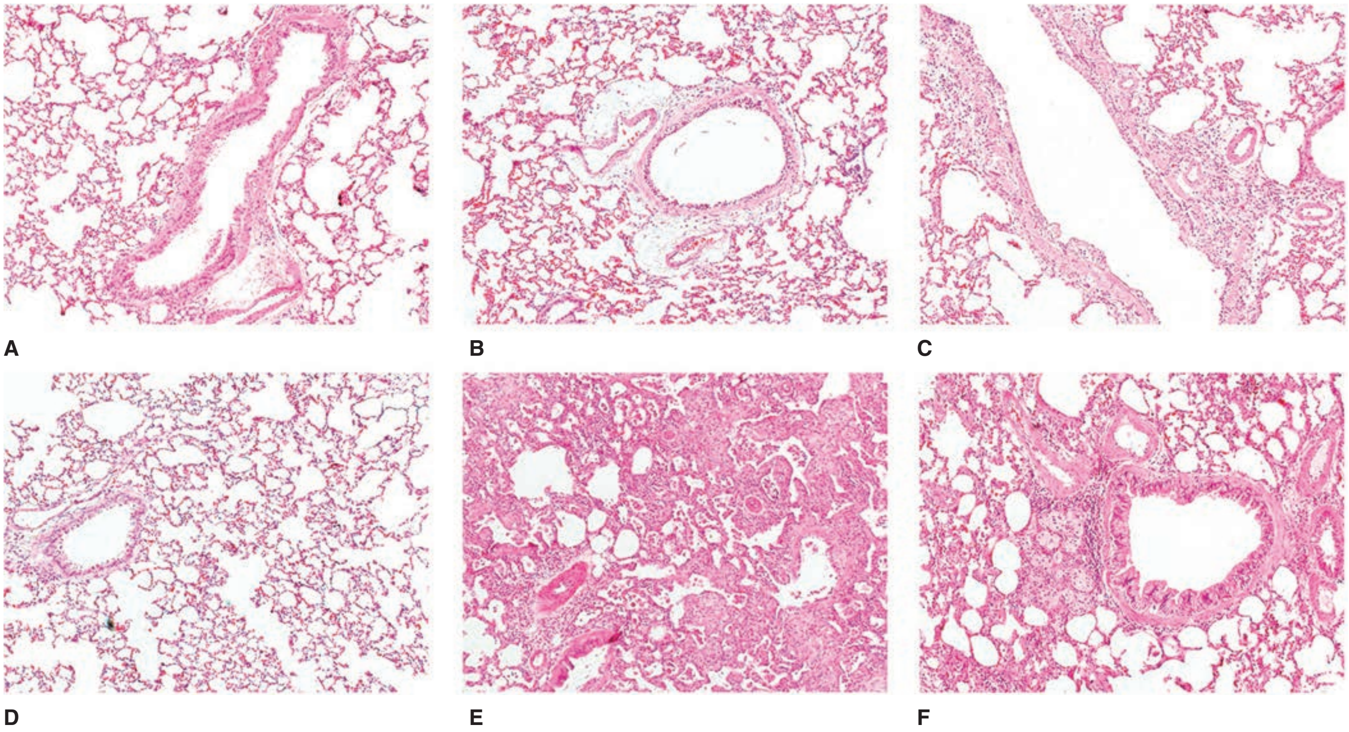

Figure 90-4 Histopathologic changes subsequent to sulfur dioxide exposure in rats. **A.** Healthy control rats not exposed to sulfur dioxide. **B–E.** Experimental rats were exposed to 2200 ppm sulfur dioxide to assess histopathologic changes after 5 h (**B**), 24 h (**C**), 14 days (**D** and **E**), and 28 days (**F**). Tissue sections were stained with hematoxylin–eosin and photos were taken at 40× magnification using light microscopy. *(Reproduced with permission from Wigenstam E, Elfsmark L, Bucht A, et al. Inhaled sulfur dioxide causes pulmonary and systemic inflammation leading to fibrotic respiratory disease in a rat model of chemical-induced lung injury. Toxicology. 2016;28–36.)*

Nitrogen dioxide (NO_2) inevitably forms when patients are administered inhaled nitric oxide (NO) via compressed gas delivery systems. The nitric oxide can react with the oxygen-rich compressed gas to form nitrogen dioxide, which can directly damage respiratory epithelial tissue.[112] Once inside the respiratory tree, nitrogen dioxide is hydrolyzed by the water on mucosal surfaces to form nitric and nitrous acids, which cause direct tissue damage. However, much of its toxicity is explained via the free radical activity of nitrogen dioxide itself and the nitrites and nitrates that derive from it.[113] Although the predominant site of toxicity from nitrogen dioxide exposure is the interface of the terminal bronchioles and alveolar membranes,[114] the relative insolubility of nitrogen dioxide in water ensures that enough gas penetrates the upper airways such that injury can occur virtually anywhere along the respiratory tract.[115] Nitrogen dioxide itself is a reactive nitrogen species that, along with other reactive derivatives, is capable of lipid peroxidation and protein oxidation,[116] both of which may be significant contributors to the gas's toxicity via disruption of the cell membrane. Mice with defective Toll-like receptor 4 expression exhibit a lessened response to nitrogen dioxide exposure compared to wild type mice,[11] suggesting that the patient's innate immunity may play a role in disease development. There is also evidence that nitrogen dioxide exposure is mutagenic to lung cells.[117]

The initial effects of nitrogen dioxide exposure are relatively benign at all but very elevated concentrations, that is, cough, fatigue, and occasionally nausea. Recent studies suggest that exposure of nitrogen dioxide in the first year of life increases the risk of persistent cough and developing asthma.[118,119] With high-intensity exposure, patients may also experience headache and chest tightness, although even these symptoms tend to resolve promptly. Nitrogen dioxide is less irritating to mucosal surfaces than other toxic inhalants. Symptoms typically abate for a period of hours before an intense pulmonary edema consistent with ARDS occurs due to increased capillary permeability following extensive damage to vascular and airway epithelium.[120] Patients who survive this are at risk for the development of bronchiolitis obliterans and cryptogenic organizing pneumonia 1 to 4 weeks following exposure.[52]

The clinical course of nitrogen dioxide toxicity demands vigilant monitoring on the part of medical personnel. Patients who are relatively asymptomatic following exposure may rapidly progress to ARDS within hours or severe obstructive bronchiolitis obliterans within weeks. Treatment is largely supportive. In animal studies, antioxidant administration has proved protective against lung injury following nitrogen dioxide exposure,[121] suggesting that aerosolized antioxidant medications are potentially of some utility in humans. Interestingly, nitric oxide (NO) has been used successfully as a pulmonary vasodilator in the treatment of ARDS following acute nitrogen dioxide toxicity.[103] Individuals who survive the initial lung injury still require close following with serial assessment of pulmonary mechanics and gas exchange over the ensuing several weeks. Patients exhibiting evidence of progressive airflow obstruction may benefit from corticosteroids to prevent or decrease the severity of BO.[122]

■ Phosgene

Phosgene (carbonyl chloride, $COCl_2$), like nitrogen dioxide, has relatively low water solubility and penetrates deeply into the alveolar spaces. It is colorless, lacks a strong odor (in high concentrations it is reported to smell like moldy hay), and is not irritating to the nasal and oral mucosa. These traits were notoriously exploited in World War I, when phosgene was used by both sides of the conflict as a weapon, resulting in tens of thousands of fatalities.[123] Modern uses include the production of pesticides, polyurethane resin, toluene diisocyanate, pharmaceutical products, and dyes. It can also be produced accidentally via the heat decomposition of various solvents, paint removers, dry cleaning fluids, and methylene chloride.[124,125] Small amounts can naturally occur from the breakdown and combustion of organochlorine compounds, such as those used in refrigeration systems.

Phosgene reacts with water to form hydrochloric acid and carbon dioxide, but its limited solubility results in little hydrolysis in the upper airways. In the relatively moist alveolar air spaces, however, the resulting acid is destructive of alveolar walls and small vessels, resulting in epithelial necrosis. In a rat model of phosgene-induced acute lung injury, stimulation of nociceptive vagal receptors was detected followed by marked decreases in minute ventilation, V/Q mismatch, and progressive pulmonary edema.[126] Phosgene's lack of irritability in the upper airways precludes the reflex bronchoconstriction provoked by other toxic gases, ensuring open passage of the gas to the alveoli. Phosgene also causes tissue damage by rapidly acetylating the amino, hydroxyl, and sulfhydryl groups of proteins, resulting in protein denaturation and structural compromise of cell membranes,[127] leading to a breakdown of the blood–air interface. Lipid membrane breakdown can occur in erythrocytes as hemolysis has been demonstrated in a mouse model of phosgene toxicity; release of intracellular erythrocyte proteins such as heme has been proposed as a potential biomarker for phosgene toxicity.[128] Lipid peroxidation also has been shown to occur, and antioxidant therapy has been shown to attenuate phosgene's effects in animal models.[129]

On exposure to phosgene, patients may experience chest tightness, wheezing, or cough; some victims experience no immediate symptoms. Following exposure, the patient experiences a latent period of 30 minutes to 8 hours before the onset of symptoms. The duration of this latent period is thought to be inversely proportional to both the severity of exposure and the ensuing severity of disease.[130] The latent period is typically followed by pulmonary edema: the patient experiences dyspnea, cough, and respiratory distress, and rales and cyanosis are appreciable on physical exam. Although survival for patients with acute phosgene exposure is good, numerous long-term sequelae have been reported, including prolonged exertional dyspnea, chronic bronchitis, and emphysema.[131]

During the latent period following exposure, numerous therapeutic options exist that may prevent or lessen the severity of pulmonary edema. Early intervention with antioxidant (N-acetylcysteine) has been shown to be beneficial in animal models by reducing free radical species and preventing biologic mediator–induced inflammation.[129] Ibuprofen, aminophylline, and isoproterenol have all proved beneficial in animal models.[132] Corticosteroids are frequently used but are of unproven benefit.[130] There is no benefit from nebulized steroid when administered 1 hour after exposure, or methylprednisolone if administered intravenously $\geq$6 hours after exposure. Intravenous bolus of high-dose corticosteroid (e.g., methylprednisolone 1 g) may be considered if presentation is <6 hours, although no experimental data are available.[133] The experiments from animal models suggested nebulized furosemide for pulmonary edema should be avoided following phosgene exposure.[134] Nebulized salbutamol treatment following phosgene also is not recommended.[135]

■ Ozone

Ozone (O_3) is a colorless, odorless gas of low water solubility. It is found throughout the atmosphere and occurs in greatest concentrations in the stratosphere, where it is protective against ultraviolet radiation. It is the main oxidant pollutant in smog and can reach hazardous levels at ground levels on days with elevated atmospheric temperature. Atmospheric levels are known to aggravate chronic lung diseases such as asthma[136] and chronic obstructive pulmonary disease.[137] Acute toxic exposures are associated with its uses in industry, including bleaching of fabrics, disinfecting water and surfaces, and the manufacture of plastics. Reports of acute ozone exposure have been reported in an airplane cabin on a high-altitude flight.[138]

Ozone is extremely reactive, and is almost entirely consumed before crossing a single bilayer membrane.[139] It results in the formation of reactive nitrogen species[140,141] and probably causes toxicity via the oxidation of membrane lipids.[142] Pre-exposure to ozone resulted in enhanced airway hyperresponsiveness, increased concentrations of total protein and proinflammatory cytokines in whole-lung lavage, and reduced inflammatory cell recruitment to the lower airways. Molecular mechanisms include enhancement of LPS and LTA-mediated signaling in lung tissue.[143,144] Animal studies suggest age-dependent effects of ozone toxicity as well as TLR-4 mediated inflammation. The cytokine CXCL5 was consistently upregulated in mice exposed to ozone, and TLR-$4^{-/-}$ mice demonstrated attenuated ozone-induced neutrophil recruitment.[145] Studies in humans have shown that exposure to ambient levels of ozone can selectively impair epithelial permeability,[146] and that this loss of epithelial integrity is parallel to, but not necessarily coupled with, increased inflammation in the lower respiratory tract.[147,148] Ozone induces epithelial necrosis and airway inflammation[148] and in severe exposures can cause dyspnea, cyanosis, and pulmonary edema. A genetic component to the response to ozone through innate immune signaling has been reported.[149] Treatment is supportive and no specific therapies have been shown to be beneficial.

■ Cadmium

Cadmium is a highly corrosion-resistant metal with many industrial applications. Most cadmium is used in nickel-cadmium batteries, but it is also found in alkaline accumulators, electroplating, bearings, solder, and as a barrier around nuclear fission generators. It is present in many metal ores, and cadmium-containing pigments are used in paints, artists' colors, rubber, plastics, printing inks, wallpaper, leather, glass, and enamels. Most inhalations occur in workers who are involved with soldering, brazing, smelting, and refining.[150] The heating of sheet metal electroplated in a cadmium cyanide bath has been reported to cause cadmium toxicity.[151] It is also important to point out that cadmium can be found in cigarettes—the heavy metal naturally accumulates in the tobacco leaf, upwards of 1 to 2 μg per gram dry weight resulting in 0.5 to 1.0 μg per cigarette.[152] Therefore, smokers may be at an elevated risk for cadmium toxicity.

The mechanisms involved with the acute lung injury due to cadmium inhalation are not well defined. Some studies suggested that cadmium-induced alveolar cell apoptosis is mediated by FasL and caspase-dependent mitochondrial apoptosis pathways in animal models.[153] Decreased adhesion of molecular E-cadherin in epithelial cells of the alveoli and small bronchioles and of VE-cadherin in vascular endothelial cells were found in mice models post exposure to cadmium.[154] *In vitro* experiments demonstrated that human fibroblasts express proinflammatory cytokines (CXCL3, CXCL3, IL-8, and IL-6) after 7 μM cadmium exposure for 7 hours.[155] Postmortem examinations of individuals who died after accidental acute inhalation exposure have revealed tracheobronchitis, consolidated lungs, denuded bronchial epithelium, intra-alveolar hemorrhage, and the presence of macrophages in the alveolar spaces.[156] It is known that cadmium inhibits the synthesis of plasma α1-antitrypsin,[157] which may explain the correlation between cadmium exposure and the later development of emphysema.[158] Rats exposed to cadmium fumes and cadmium chloride aerosols develop pulmonary edema and on necropsy show increased numbers of alveolar type II cells.[150]

When cadmium-containing materials are heated, cadmium vapors and cadmium oxide fumes are released. Patients who are exposed initially present similarly to those with metal fume fever (see below): they are asymptomatic for several hours before developing fever, malaise, and myalgias.[150] These constitutional symptoms are often accompanied by, or shortly followed by, respiratory distress, including cough, chest tightness, and dyspnea. Cadmium may be detected in the urine if the identity of the toxin is uncertain.[159] Acute cadmium toxicity has been shown to cause interstitial pneumonitis,[160] and fatal cases have been remarkable for initial pneumonitis that relentlessly progresses to ARDS and eventual death from respiratory failure.[156] Management is supportive; there are no specific treatments for cadmium inhalation. Formoterol and ipratropium bromide have been shown to partially protect the lungs against inflammation by reducing neutrophilic infiltration in rats.[161]

■ Mercury

Although mercury is poorly soluble in distilled water, its solubility increases in contact with plasma or whole blood, as at the blood–air interface. Sources of mercury gas exposure are primarily industrial and include ore smelting, cement production, fur and felt hat manufacture, fossil fuel combustion, and gold extraction. Mercury is found within the silver amalgam used by dentists, and a number of exposures, including several with fatal outcomes, have occurred in the home during amateur attempts to extract precious metals from amalgams that also contain mercury.[162,163] There is literature to support reports of people developing acute lung injury after being exposed to spilled mercury from breaking a thermometer in the home setting.[164]

Like phosgene and cadmium, mercury vapor has little or no immediate upper airway or mucosal surface irritant effects, and as a result exposed individuals may inadvertently remain in an area where the harmful vapors are present. The fatal level of mercury vapor to humans is not known. An exposure to more than 1 to 2 mg/m^3 of elemental mercury vapor for a few hours causes acute chemical bronchiolitis and pneumonitis.[158] Typical clinical presentations include symptoms of cough, dyspnea, and respiratory distress that develop 12 to 24 hours post-exposure. These initial symptoms are sometimes accompanied by fever, nausea, vomiting, diarrhea, and a metallic taste in the mouth, similar to what is often experienced by individuals with metal fume fever and associated transient pneumonitis. In fact, mercury vapor inhalation can be mistaken for metal fume fever or influenza. Symptoms of mercury vapor inhalation do not, however, spontaneously resolve as with metal fume fever. Instead, the pneumonitis may progress to ARDS; death has been preceded in several reports by tension pneumothorax.[163,165] The toxicity of mercury vapors within the lung is thought to be due in part to the irritant effects of oxidized mercurous and mercuric ions[166] and to the disruption of enzyme systems containing sulfhydryl groups.[163] Mercury coagulates protein, blocks cellular metabolism of carbohydrates at the pyruvic oxidase level, and as a result produces a metabolic acidosis.[162] Lung pathology following acute exposure reveals pulmonary edema, capillary damage, and the desquamation and proliferation of airway epithelium followed by an obliteration of airspaces.[167] Early CT imaging in patients with acute mercury poisoning reveals ground-glass opacification, alveolar consolidation, and ill-defined nodules. These abnormalities were resolved in follow-up CT scans after 30 days of exposure.[168] Inhaled mercury vapor is absorbed rapidly into the blood, where it can achieve systemic toxicity; renal, hepatic, and nervous system pathology have been reported.[169,170] Patients surviving the acute injury typically experience resolution of their symptoms within a week following onset, but some have also progressed to develop interstitial fibrosis.[171,172] Mortality due to exposure may be increased in children.[173]

Blood levels of mercury may reflect acute uptake, and urine levels can monitor chronic stores. Treatment of mercury inhalation is supportive and addresses the acute lung injury. Mechanical ventilation, including positive pressure and high-frequency oscillating ventilation, may be beneficial in the treatment of mercury-induced ARDS.[173] Early vigorous administration of steroids can decrease the inflammation and delay or prevent the progression to severe interstitial pulmonary fibrosis in mildly affected patients.[174] Chelating agents, such as dimercaprol and D-penicillamine, are frequently used to increase the rate of mercury excretion after ingestion but have not been shown to affect the outcome of the acute lung injury.[163,174]

■ Zinc Chloride

Zinc chloride ($ZnCl_2$, or hexite) is odorless, a major ingredient of smoke bombs and smoke-generating devices and has been responsible for numerous toxic and fatal exposures.[175–178] The compound forms when zinc oxide is ignited with hexachloroethane. Toxic inhalations have occurred in settings in which individuals have inhaled smoke in confined spaces, in most instances without a functional protective breathing apparatus. The smoke effect tends to contribute to the duration of exposure by obscuring vision, sometimes resulting in directional disorientation and the inability to quickly escape the area of exposure.

When inhaled, zinc chloride is in particulate form with an average particle size of 0.1 μm, small enough to allow large amounts of it to penetrate through to the lower respiratory tract. After depositing on the airway and alveolar surfaces, zinc chloride reacts with water to form hydrochloric acid and zinc oxychloride. This directly causes irritation of exposed mucosal surfaces and is the probable mechanism behind the diffuse lung injury observed on exposure.[179] The irritation of the mucous membrane of the respiratory tract leads to symptoms that include burning sensation, coughing, wheezing, laryngitis, shortness of breath, headache, nausea, and vomiting.

Zinc chloride inhalation is commonly followed by tracheobronchitis and pneumonitis, reflecting the sites of particle deposition. Patients experience cough, dyspnea, and chest tightness followed by a period of relative stabilization before progressing to ARDS.[176–178] Chest imaging may be initially normal but can reveal pleural effusions, pneumomediastinum, and bilateral infiltrates consistent with pneumonitis. There is evidence that prominence of ground glass opacities observed on high-resolution CT imaging is predictive of both severity of exposure and length of hospital stay.[178]

A urine zinc level may confirm the diagnosis of zinc inhalation toxicity. There is evidence that measuring serum zinc levels may be of prognostic value for patients who have inhaled zinc chloride from smoke bombs.[180] Patients should be monitored for progression to ARDS and treated with supplemental oxygen and mechanical ventilation if indicated. The administration of high doses of N-acetylcysteine may accelerate systemic zinc clearance[181] and thereby spare some oxidant-induced lung injury, but this is unsupported by clinical experience.[176] Since zinc inhalation is locally deposited in the respiratory tract rather than in systemic zinc overdose, the effect of N-acetylcysteine is questionable.[181] Corticosteroid use is similarly controversial. The aim to reduce overwhelming inflammation by early administration of intravenous steroid was offset by the risk of ARDS in patients with sepsis.[182]

■ Mace and Tear Gas

"Tear gas" is actually not a gas, but rather, a compound of toxic chemical irritants collectively given the names chloroacetophenone (CN or "chemical mace"), *ortho*-chlorobenzylidene malononitrile (CS), and oleoresin capsicum (OC or "pepper spray"). All three agents are used by military and law enforcement agencies to control crowds and individuals because of the irritants' intense and immediate effects on mucus membranes and lacrimal glands. Exposure to any of them results in immediate rhinorrhea, mucositis, chemical conjunctivitis, and profuse lacrimation.[183,184] Immediate pulmonary effects include an intense burning sensation in the upper airways, reflex airway constriction, chest tightness, dyspnea, and cough. Exposure may also provoke nausea, headache, and photophobia. Delayed contact allergy, leukodermia, or exacerbation of pre-existing dermatitis also have been described in case reports.[185] Severity of response depends on the concentration of the agent used, the duration of exposure, and the presence or absence of ventilation and protective breathing apparatus.

The effects of tear gas are predominantly due to its upper airway irritant effects, and thus, lower airway injury and parenchymal disease are rarely observed. Auscultation of the chest is typically clear, and the chest radiograph is usually without abnormality. Case reports of severe pulmonary disease exist, describing pneumonitis, pulmonary edema, reactive airways dysfunction syndrome, and acute bronchospasm in an asthmatic.[186–189] These cases have in common prolonged periods of exposure with poor ventilation. A fatal hypersensitivity reaction to CS has been reported.[190]

Due to the possible secondary contamination of healthcare staff, the initial medical management of patients exposed to tear gases consists primarily of nonspecific chemical decontamination and symptomatic therapy.[191] The most immediate concern in the treatment of tear gas exposure is maintenance of a patent airway. Mucosal surfaces should be irrigated profusely, and suction may be useful in clearing the copious oral and nasal secretions that may compromise the airway. Humidified O_2 should be administered. Beta-agonists and ipratropium aerosols should be used in the presence of bronchospasm;[192,193] no benefit from corticosteroids has been observed. Patients with prolonged or intense exposure should be monitored carefully for evidence of progression to significant respiratory disease.

ELECTRONIC CIGARETTES AND VAPING

Electronic cigarettes are one of the fastest growing tobacco products used in America today. E-cigarettes entered the market in 2007 and offered an attractive alternative to the conventional cigarette, which generates combustion-dependent toxins and is known to cause lung cancer.[194] Since 2014, e-cigarettes have become the most popular tobacco product used among the youth population, with more than 3.6 million youth using vaping products, including 1 in 5 high school students.[195] Initially thought to be the safer alternative to traditional combustible cigarettes, an emerging epidemic that was recognized in 2019 has curbed expectations regarding the safety of e-cigarettes and vaping products.

E-cigarette or vaping product–associated lung injury (EVALI) is the official term coined by the CDC to describe the clinical syndrome that was first reported to involve an unusual cluster of cases in Wisconsin of young adults with nonspecific respiratory symptoms and abnormal radiologic findings, all of whom reported vaping use in their clinical history.[195] Thereafter, new clusters arose in Utah; by January of 2020, 2711 cases of EVALI had been reported across all 50 states.[196] Sixty-four deaths were confirmed by the CDC within this time period.[197]

Although e-cigarettes were initially developed for the consumption of nicotine, e-cigarettes or vaping products are also made to aerosolize tetrahydrocannabinol (THC), the psychoactive ingredient of marijuana. Vaping has become a popular way to consume THC among the youth population, especially males. More than 85% of e-cigarette users report using products for THC consumption.[198] In a large survey of 4631 participants who use vaping products, the prevalence of THC-based product use was greatest among respondents aged 18 to 24 years (36%) and decreased with age.[198] Retrospective studies of patients with EVALI show a higher odds ratio of exclusive use of THC-containing products. In a smaller study of 51 patients with a clinical diagnosis of EVALI, 47 had detectable THC from bronchoalveolar lavage or reported using THC-based devices.[199] These studies suggest that THC-based products are at least as dangerous for developing EVALI as nicotine-based devices.

The components of an electronic cigarette include a battery that powers a heating coil and an atomizer that transforms the e-liquid into an inhalable aerosol.[200] The aerosolized particles are on the order of nanoscale diameter ranging from 11 nm to 25 nm but may be as large as 96 nm to 175 nm.[201] The aerosolized particles are sufficiently small to reach the alveoli, where they can diffuse across the alveolar–capillary interface and enter the bloodstream.

The e-liquid typically contains high levels of nicotine, explaining the incredible addiction potential, as well as flavoring products and humectants. Propylene glycol and glycerol are ingredients added in the e-liquid to act as a vehicle to deliver the active ingredients in solution to the user. However, the additional components in the e-liquid are numerous. Tobacco-specific nitrosamines (TSNAs), aldehydes, metals, volatile organic compounds (VOCs), phenolic compounds, polycyclic aromatic hydrocarbons, flavorings, and tobacco alkaloids represent the potentially hazardous materials found in e-cigarettes that are capable of causing pulmonary disease.[200]

TSNAs are generated during the curing process of the tobacco plant and are known carcinogens.[202] Studies have utilized mass spectrometry to measure specific TSNAs, such as *N′*-nitrosonornicotine, and have reported low levels (60 μg/L) in e-cigarette products.[203] When the e-liquid is superheated, toxic carbonyl-containing compounds are produced, including formaldehyde and acetaldehyde, which have been shown to be carcinogens by the International Agency for Research on Cancer.[204] Other carbonyl-containing compounds, such as acrolein, can be produced and have been shown to cause nasal irritation and respiratory epithelial lung damage.[200] Volatile organic compounds include alcohols and phenols that can be a health hazard to the user.

Investigators have analyzed commercially available e-cigarettes and detected concentrations of benzene, methanol, and ethanol that exceeded their authorized maximum limits as residual solvents, as defined by pharmaceutical product guidelines.[205] Additional VOCs reported to be found in e-cigarettes include toluene, xylenes, and ethyl acetate.[205]

Heavy ionized metals are also found in the inhalable aerosols of e-cigarettes. Mass-spectrometry experiments using several brands of e-cigarettes revealed that cadmium, chromium, lead, manganese, and nickel are all present in e-liquids.[206] Additionally, metals from the heating coil such as aluminum, lead, nickel, cadmium, chromium, and tin can be liberated and aerosolized during inhalation.[207] It has been reported that urine and saliva samples can be collected for detection of nickel and chromium as noninvasive biomarkers of heavy metal toxicity from e-cigarette use.[208]

More than 7000 diverse e-liquid flavors are available for users, yet many sellers of e-cigarettes fail to include the flavoring ingredients on the package labels.[209] Flavorings are a popular modification to e-cigarettes that users report as being more enjoyable than traditional tobacco cigarettes.[210] Compounds such as saccharides can be added to the e-liquid to generate a sweet taste; however, when the saccharides are heated by the coil they may produce furans and carbonyl-containing aldehydes leading to respiratory epithelial damage.[211] Specific compounds such as diacetyl and acetoin are used in industry to make unique flavor variants such as butterscotch, caramel, and piña colada flavors. Volatile diacetyl compounds have previously been reported to cause bronchiolitis obliterans in a microwave-popcorn production plant.[212]

The exact compounds directly responsible for the EVALI epidemic that arose in 2019 are not completely clear. Clinical data analysis of bronchoaveloar gavage samples from people with EVALI revealed that vitamin E acetate (VEA), a compound commonly found in dietary supplements and skin creams, was detectable in 94% of patients with EVALI.[199] To determine if there is a causal link between VEA and EVALI, investigators developed a mouse model of VEA exposure in an aerosolized form. Compared with the control group, bronchoaveloar gavage samples from mice exposed to VEA for 2 weeks demonstrated increased albumin, suggesting epithelial damage, increased CD45$^+$ leukocyte abundance, and increased lipid-laden macrophages consistent with bronchoaveloar gavage samples taken from patients with EVALI.[197] These studies strengthen the argument that VEA may be a specific factor driving the development of EVALI, but it is likely that a combination of factors contribute to the clinical syndrome in its entirety.

The underlying pathogenesis of vaping-induced lung injury is incompletely understood. Several studies have identified mechanisms that are likely to be directly involved in respiratory tissue damage. Redox imbalance and inflammation have been consistently shown to be a mediator of lung damage attributed to e-cigarettes. *In vitro* studies exposing human airway epithelial cells to e-cigarette aerosols showed increased production of proinflammatory cytokines such as IL-6 and IL-8.[218] Mice exposed to aerosols from popular e-cigarette products demonstrated depleted lung-specific glutathione levels, which are critical for maintaining redox balance.[213] A separate study reported that free radicals are detected at upward of 7×10^{11} per puff.[219] Furthermore, mice exposed to e-cigarette aerosols for 2 weeks developed macrophage-mediated inflammation and markers of oxidative stress. The mice exposed to e-cigarette aerosols also demonstrated impaired bacterial clearance of intranasal infection using *Streptococcus pneumoniae* compared with mice breathing room air, suggesting that e-cigarettes can affect the immune system.[214]

Mitochondrial oxidative stress and direct DNA damage also are implicated in the pathogenesis of e-cigarette aerosols. Human lung fibroblasts exposed to e-cigarette aerosols containing copper nanoparticles demonstrated increased mitochondrial reactive oxygen species and subsequent instability of the electron transport chain protein complex IV, as well as fragmentation of genomic DNA.[215] While more studies are needed to fully delineate the pathogenesis of lung injury caused by e-cigarette aerosols, it is clear that inflammation, oxidative stress, and immune dysregulation are implicated in the cellular pathophysiology.

The clinical course of EVALI consistently involves shortness of breath, dry cough, chest tightness, pleuritic chest pain, and occasionally hemoptysis.[195,216] Gastrointestinal complaints are not uncommon—abdominal pain, nausea and vomiting, and diarrhea were described by 77% of patients from medical chart abstraction reviews completed by the CDC.[216] Constitutional symptoms, such as fever, chills, and weight loss, may be complaints described by patients with EVALI as well.

Radiologic findings typically show diffuse hazy infiltrates or areas of consolidation by chest radiograph.[195] CT imaging reveals a pattern consistent with acute lung injury and, possibly, organizing pneumonia (Fig. 90-5).[217]

Bronchoalveolar lavage typically demonstrates neutrophilic and eosinophilic infiltrates, but these findings can be nonspecific.[218] Biopsy specimens demonstrate peribronchiolar inflammation accompanied by foamy macrophages (Fig. 90-6).

EVALI is considered a diagnosis of exclusion. A careful patient history and thorough physical examination are critical to make the diagnosis of EVALI. Treatment of EVALI typically includes initiation of empiric antibiotics to cover for community-acquired pneumonia, which is much more common than EVALI. Corticosteroids, such as methylprednisolone, have been used to treat patients with EVALI, although the efficacy of this treatment has not been formally studied[218] and is not recommended.

SYSTEMIC ILLNESS FROM INHALED TOXINS

While most of this chapter has focused on local effects within the pulmonary system, systemic, flu-like illness has been observed in patients exposed to organic dusts and fumes of heated metals and fluorocarbons. The disease course is self-limited and, in all cases, appears to be cytokine-mediated.

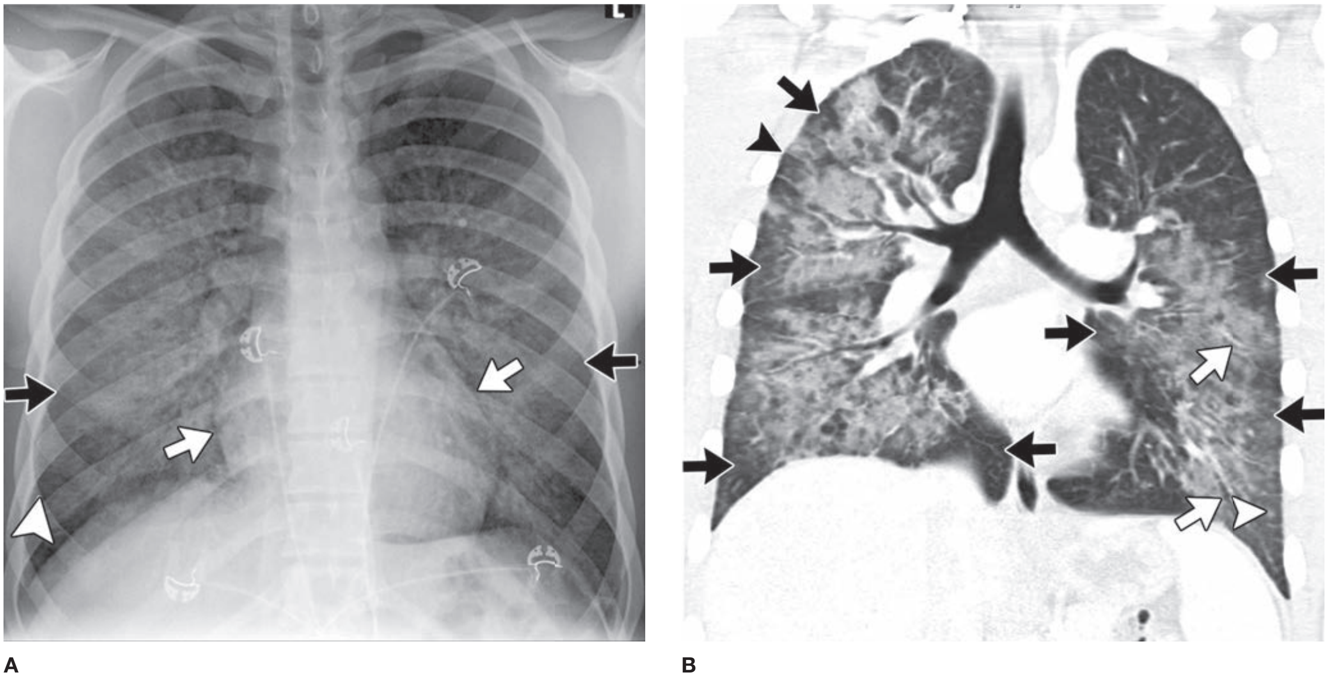

Figure 90-5 Radiologic images from an 18-year-old presenting with fever of 103°F and vomiting for 3 days. History notable for nicotine and tetrahydrocannabinol vaping. The findings demonstrate EVALI complicated by an organizing pneumonia pattern. **A.** Posteroanterior radiograph reveals perihilar hazy opacities with sparing of the heart border *(white arrows)* and periphery *(black arrows)*. Septal thickening is remarkable *(arrowhead)*. **B.** Corresponding CT image shows perihilar ground-glass opacities with prominent sparing of subpleural interstitium, both peripherally and centrally *(black arrows)* and intermixed areas of lobular sparing. There is also sparing of peribronchovascular interstitium *(white arrows)*. Septal thickening *(black arrowhead)* and scattered centrilobular nodules are present *(white arrowhead)*. Corticosteroid administration rapidly improved the patient's condition. *(Reproduced with permission from Kligerman S, Raptis C, Larsen B, et al. Radiologic, Pathologic, Clinical, and Physiologic Findings of Electronic Cigarette or Vaping Product Use-associated Lung Injury (EVALI): Evolving Knowledge and Remaining Questions. Radiology. 2020;294(3):491–505.)*

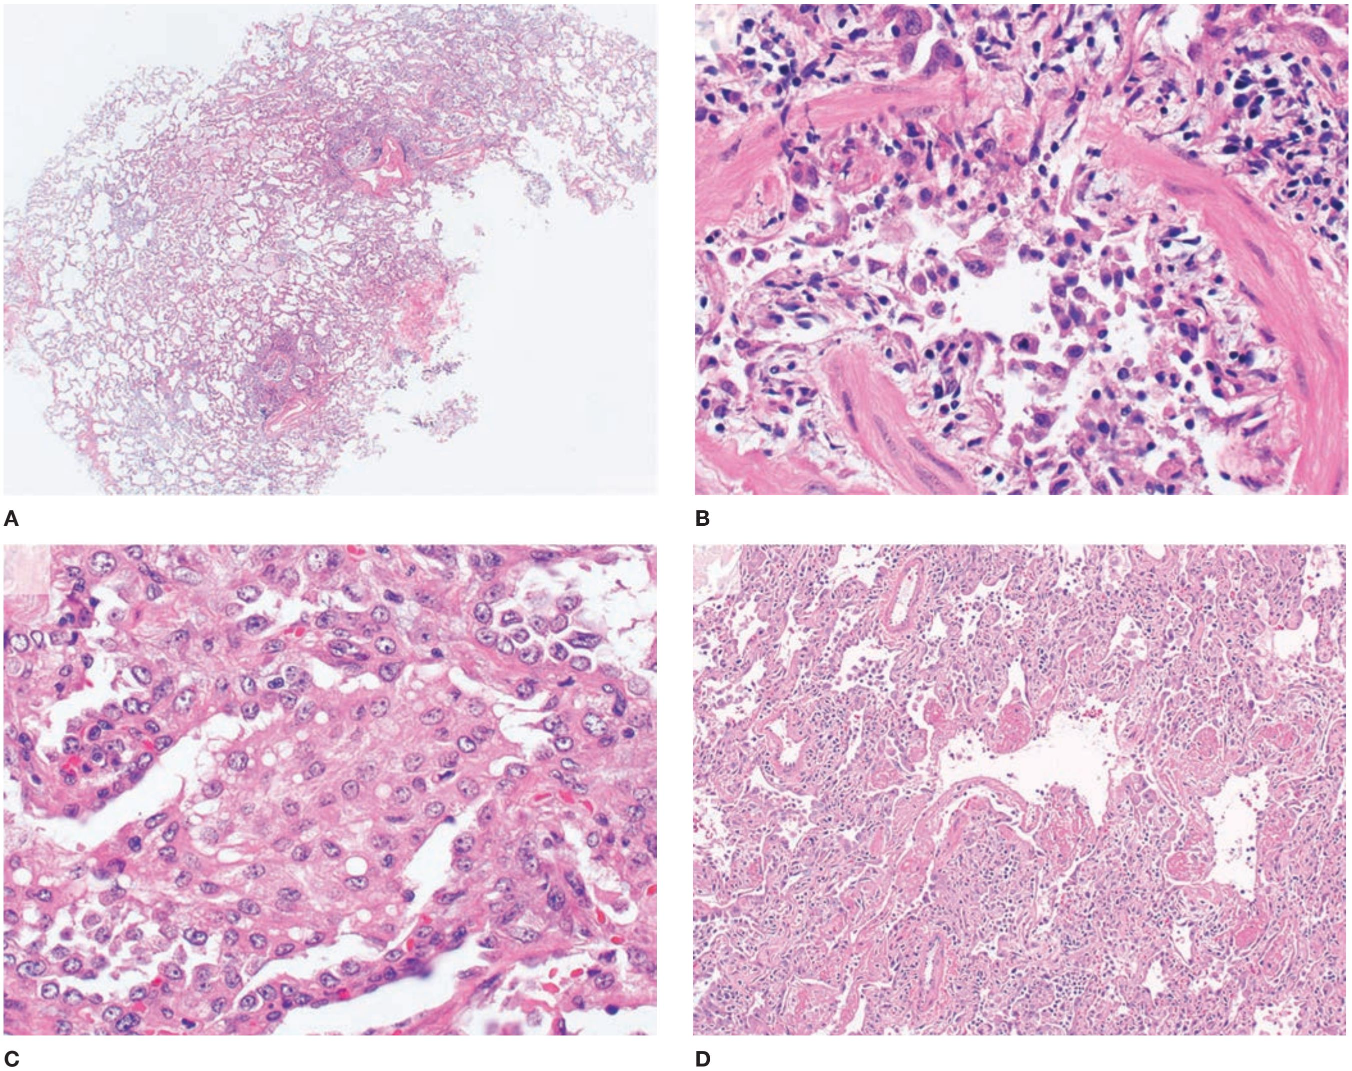

Figure 90-6 Representative biopsy specimen from a patient with EVALI. **A–B.** Cases predominantly show airway-centered acute lung injury co-presenting with severe bronchiolitis accompanied by mucosal edema, sloughing of bronchiolar epithelium, and peribronchiolar organization. **C.** All cases demonstrated foamy or vacuolated macrophage accumulation in peribronchiolar airspaces accompanied by pneumocyte vacuolization. **D.** In some instances, severe injury with diffuse alveolar damage and hyaline membranes is observed—a finding associated with a poor outcome. *(Reproduced with permission from Butt YM, Smith ML, Tazelaar HD, et al. Pathology of Vaping-Associated Lung Injury. N Engl J Med. 2019;381(18):1780–1781.)*

■ Metal Fume Fever

Since its first description by Potissier in 1822,[219] metal fume fever has been known by a number of other names: brazier's disease, spelter shakes, brass chills, zinc chills, welder's ague, copper fever, foundry fever, and Monday morning fever. It is a self-limited, flu-like syndrome characterized by the delayed onset of fever, chills, myalgias, and generalized malaise following exposure to fumes that contain metal oxides. Specific fumes that have been implicated include those of beryllium, cadmium, copper, magnesium, nickel, silver, and zinc. Metal fume fever is an occupational disease; welders are at the highest risk for developing metal fume fever, although it has been reported in other metalworking occupations including soldering, brazing, cutting, metallizing, forging, melting, and casting.[220] Episodes of varying severity of metal fume fever may be experienced by between 20% and 35% of all welders.[221,222] Exposure is typically associated with confined spaces and poor ventilation. It is estimated that 1500 to 2500 cases of metal fume fever occur each year in the United States.[220,223]

The typical course of metal fume fever begins with sensations of dry throat and a sweet or metallic taste. Fever, chills, and myalgias develop from 4 to 8 hours after exposure and spontaneously resolve within 48 hours. Respiratory-related symptoms of chest tightness, nonproductive cough, and dyspnea are sometimes observed. Laboratory findings are remarkable for transient leukocytosis; chest x-ray is typically normal, although findings consistent with pneumonitis have been observed. Pulmonary function tests are usually normal, but obstructive and restrictive deficits, as well as abnormalities of diffusion, have been reported.

Repeated exposure appears to lead to tachyphylaxis; however, this tolerance is transient and only persists through the work week. The name "Monday morning fever" refers to the recurrence of acute disease on return to exposure following a short period of absence.[224] A proposed mechanism of the observed tolerance to metal fumes involves the increased synthesis of the toxic metal-binding protein metallothionein in exposed patients.[225] The disease has been mistaken for influenza, atypical or community-acquired pneumonia, and a malaria-like illness because of overlapping presenting symptoms. The diagnosis is based primarily upon a history of exposure to metal oxide fumes. Metal fume fever is generally thought to have no long-term sequelae. An association between it and the later development of occupational asthma has been observed,[222] but a prospective study failed to show that a history of metal fume fever is predictive of later bronchial hyperresponsiveness.[226]

The pathogenesis of metal fume fever appears to involve an increase in proinflammatory cytokine activity in the lung; increased bronchoalveolar lavage fluid concentrations of tumor necrosis factor (TNF), interleukin 6 (IL-6), and IL-8 have been reported in subjects exposed to zinc oxide fumes,[227] probably produced by pulmonary macrophages.[228] Following exposure, bronchoalveolar lavage TNF-α levels peak earlier than other cytokines, suggesting that its role may be central to disease progression.[229] Of the numerous components of metal fumes, it appears to be the soluble transition metal particles, which generate reactive oxygen species and deplete glutathione stores, that are responsible for the fumes' cytotoxicity.[230] Recent studies used whole-blood assay (WBA) to more reliably understand the blood-immune response to metal fumes from a systems level. Using whole-blood samples, these results support earlier studies as they show dose-dependent increases in levels of IL-6, IL-8, TNF-α, and IL-1β after 24 hours of exposure to copper- and zinc-containing fumes.[231] These data support the hypothesis that metal fume fever is an acute systemic inflammatory reaction. *In vitro* studies show that inhibition of protein tyrosine phosphatase 1B (PTP1B) demonstrated enhanced increase in cytokine levels; PTP1B was identified as a pathway that can be attributed to the effects of zinc and copper welding fumes and therefore can explain some of the mechanisms underlying welding fume fever.[231] Gene expression profiling of lung injury following welding fume exposure in a monkey model has been reported to aid in understanding the inflammatory response of lung tissues.[232]

Treatment of metal fume fever is supportive, including bedrest, antipyretics, and analgesics. Metal fume fever must be distinguished from acute metal fume toxicity, as with cadmium or mercury, which can present similarly to metal fume fever but fails to resolve and instead progresses to respiratory distress. Prevention of metal fume fever involves provision of adequate ventilation, fume removal devices, and respiratory protection for workers in environments where metal oxide fumes are generated.

■ Polymer Fume Fever

A syndrome similar to but less common than metal fume fever, polymer fume fever was first reported in 1951.[233] Fluorocarbon polymers are a class of compounds that are commonly used as nonstick coatings on cooking equipment (polytetrafluoroethylene [PTFE, or Teflon] is a famous example) but are also used as mold-release sprays, lubricants, and fabric or leather treatments.[234] When fluorocarbon polymers are heated to greater than 300°C, fumes are produced that include carbonyl fluoride, perfluorinated alkanes, hydrofluoric acid, and carbon dioxide.[234] Extremely small particles capable of reaching alveolar units also may contribute to disease progression.[235]

Polymer fume fever presents similarly to metal fume fever: initial symptoms include dry throat, rhinitis, chest tightness, and conjunctivitis. Constitutional symptoms (fever, chills, myalgias) typically follow exposure by about 4 to 8 hours and spontaneously resolve within 1 day. As with metal fume fever, a leukocytosis is observed concurrent with the patient's constitutional symptoms. Individuals with preexisting obstructive lung disease may experience worsening obstruction after recurrent exposures to polymer fumes.[236] Notable differences between metal fume fever and polymer fume fever are important to consider. Pneumonitis is more frequently observed in polymer fume fever than with metal fume fever, perhaps due to release of hydrofluoric acid. Tachyphylaxis, a hallmark observation of metal fume fever, is not observed in polymer fume fever, suggesting that different mechanisms are responsible for the two diseases.[236] As with metal fume fever, the systemic response to particle inhalation appears to be cytokine-mediated.[237]

Although exposure to pyrolyzed fluoropolymers occurs mainly in industrial settings, it also occurs in homes and via less obvious means of exposure. In one report, within an hour of an empty PTFE-coated pan being heated on a stove, five exposed pet birds died and their owner contracted polymer fume fever.[238] A similar report from 2012 describes an individual who left a PTFE-coated pan on a stove for 5 h and, after noticing, quickly ran the pan under cool running water from the sink. This generated an explosive vapor of polymer fumes that was subsequently inhaled by the individual leading to constitutional symptoms hours later.[239] Numerous reports have suggested that workers with skin exposed to fluoropolymers may have contracted polymer-fume fever via smoking their self-contaminated tobacco.[240–242] Others may have contracted the disease via igniting their marijuana with cotton that had previously been impregnated with hairspray.[243] Several episodes of polymer fume fever have occurred following exposure via the waterproofing spray used on horse rugs.[244]

Treatment of polymer fume fever is supportive. Workers exposed to fluoropolymers should be provided adequate ventilation and instructed of the risk of indirect exposure via skin contamination. Strict handwashing should be required, and tobacco smoking should be especially discouraged after exposure.

■ Organic Dust Toxic Syndrome

The final systemic illness caused by inhalational exposure described here is organic dust toxic syndrome (ODTS), also known as silo unloader's syndrome, atypical farmer's lung, pulmonary mycotoxicosis, and toxic pneumonitis. As with metal fume fever and polymer fume fever, ODTS is a self-limited disease that presents with fever, chills, and myalgias several hours after exposure to the offending agent followed by spontaneous resolution within 48 hours.[245,246] However, underlying lung conditions may lead to incomplete or delayed recovery.[247]

Organic dusts are dissimilar from the fumes produced from extreme heating as seen in metal fume fever and polymer fume fever. Rather, organic dusts describe biomaterials found in agricultural settings and include hay or corn silage-containing silos, molds, spoiled animal feed, and swine confinement facilities. Agricultural workers are at the highest risk for contracting ODTS. Other settings of ODTS have included a college fraternity party in which hay was laid on the floor;[248] a storehouse containing moldy oranges;[249] a waste-sorting plant;[250] a print shop in which an air humidifier was colonized with Gram-negative bacteria, fungi, and amoebae;[251] following exposure to woodchip mulch;[252] and previously asymptomatic seafood factory workers who were exposed to shrimp shell powder containing bacterial endotoxin.[253] Lifetime risk of contracting ODTS may be around 19% for farmers with exposure to organic dust.[254]

The specific agent or agents within organic dust responsible for ODTS have not been fully characterized. An epidemiologic study in 2007 suggested contaminated mulch was implicated as the source of presumed ODTS among urban landscape workers, highlighting that ODTS is not limited to rural agricultural settings.[255] Bacterial cell wall components, endotoxin, and peptidoglycan are thought to play prominent roles.[256,257] Specifically, the polysaccharide component of the bacterial cell wall β-glucan has been demonstrated to induce Th1- and Th2-driven immune responses and may be implicated as a central antigen in ODTS.[258] Workers handling grass, cereal, or vegetable seeds are at risk of exposure to high levels of endotoxin-containing seed dust.[259] Fungal spores and *Actinomyces* also are likely contributors to pathogenicity,[260] and an ODTS-like response can be provoked with endotoxin-free grain extracts.[261] Like metal fume fever and polymer fume fever, the disease process is likely initiated or provoked by activation of the patient's innate immune system by organic dust components, such as endotoxin's activation of TLR-4. Cytokine expression increases following organic dust exposure, especially of proinflammatory cytokines such as TNF-α and IL-6,[262] suggesting a means by which local activation of innate immunity may provoke the observed systemic manifestations. IL-1 also is thought to play a critical role in ODTS development.[263] An intriguing correlation has been observed between patients with celiac disease and the development of ODTS,[264] suggesting that some underlying disorder, perhaps a hyperactivity of innate immunity, may increase a patient's susceptibility to both.

Patients with ODTS frequently present with no findings on chest exam, although bibasilar crackles and scattered wheezes may be appreciated. A neutrophil-predominant leukocytosis is frequently found, and mild hypoxemia and bilateral infiltrates on chest x-ray have been reported. Although bronchoalveolar lavage may initially reveal a predominance of neutrophils, a lymphocytic response may come to dominate the cellular population.[246]

ODTS needs to be clinically distinguished from hypersensitivity pneumonitis (HP), which is also provoked by inhaled organic dust. HP typically follows low levels of exposure after a period of sensitization, while ODTS is an acute reaction to high levels of organic dust, potentially on first exposure. HP is a restrictive process detectable by pulmonary function testing, while ODTS sometimes presents with transient airflow obstruction and often with no appreciable functional abnormality. The early bronchoalveolar gavage findings in ODTS are overwhelmingly neutrophilic, unlike the lymphocytic findings in HP.

Treatment of ODTS is supportive. Unlike with HP, corticosteroids appear to be of only marginal benefit in the treatment of ODTS.[265]

SUMMARY

Toxic inhalations can arise from numerous agents and produce a broad spectrum of pulmonary and systemic injuries. Treatment is largely supportive and should be guided by the patient's clinical status. Specific attention should be paid to the patency of the airway following acute upper airway exposures, and providers should be aware of the risk of the development of severe pulmonary disease following an asymptomatic latent period. Given the unpredictable clinical course of these exposures, a good exposure history should be taken, and cautious monitoring of exposed patients is prudent. Materials safety data sheets and the National Library of Medicine's TOXNET (*www.nlm.nih.gov/toxnet/*) are excellent information resources for specific toxins.

CHAPTER 91

High-Altitude Physiology and Clinical Disorders

Kingman P. Strohl
Cynthia M. Beall
Nikolaus C. Netzer

INTRODUCTION

Altitude is an environmental state of elevation >760 m (~2500 ft) above sea level and is a continuous physiologic stressor of hypobaric hypoxia (Fig. 91-1). Altitudes are subdivided into very high (3500–5500 m or ~11,500–18,000 ft) and extreme (>5500 m or >18,000 ft). Eighty million people live at altitude around the world, and 40 million people per year travel to an altitude ≥2500 m (~8000 ft).[1] Many more work in mines, the military, or border operations at high altitude. Clinical encounters specific to altitude result from hypoxemia (FIO_2 equivalent to ~17% O_2 at 2500 m, and ~8% O_2 at the summit of Everest), which leads to physiologic responses and illnesses. Such illnesses have been recognized and empirically treated in prehistoric native populations.[2] Birthweights are generally lower, and the rates of small-for-gestational-age babies and congenital heart defects are higher than in lowland populations.[3] With a hurried ascent, ~80% of lowlanders will report a transient headache (high-altitude headache [HAH]), and some will develop an acute high-altitude illness: acute mountain sickness (AMS). Fewer will develop high-altitude cerebral edema (HACE) and high-altitude pulmonary edema (HAPE).[3,4] HAH and AMS are annoying and interfere with activity and work; however, HACE and HAPE can be fatal, with mortality rates approaching 30%.[5–7] Some residents at altitude exhibit chronic mountain sickness (CMS) and right ventricular hypertrophy, developing over months to years of residence at altitude. Cold air and extreme exercise also may contribute to illness. Other environmental features may include UV radiation, trauma, and infections (which are not covered in this chapter). Finally, managing illness in a remote altitude location can be challenging, as evacuation to a lower altitude as a primary treatment may be limited or not feasible.

CONSIDERATIONS OF EXPOSURE AND TIME COURSE

Individual responses to low-barometric-pressure hypoxia may be conceptualized along a time continuum of interrelated phases: acute (immediate to 3–5 days in which acute illnesses present), subacute (over weeks leading toward acclimatization), chronic (years), and lifelong residence (Fig. 91-2). The reduction in environmental oxygen as result of altitude exposure lowers the oxygen available for gas exchange in the lungs (PA_{O_2}), arterial oxygen (Pa_{O_2}), and cellular oxidative phosphorylation for adenosine triphosphate (ATP) production.

Single-cell and multicellular organisms have been exposed to oxygen since the origins of life; over the past 600 million years, oxygen levels have varied from as low as ~12% to as high as ~30%.[8,9] All multicellular organisms have genetically encoded oxygen homeostasis pathways—that is, there are interacting feedback controls of cellular and organ system adaptations to oxygen availability and need. Archaic responses to hypoxia appeared several billion years ago, and elements continued, some with adaptations, to contribute to physiology and altitude fitness in modern living organisms, as well as the human ancestral tree. People moved to live at high altitudes in the past 100,000 years, and in three continents evolutionary forces have resulted in different patterns of adaptation in different indigenous populations.[10,11]

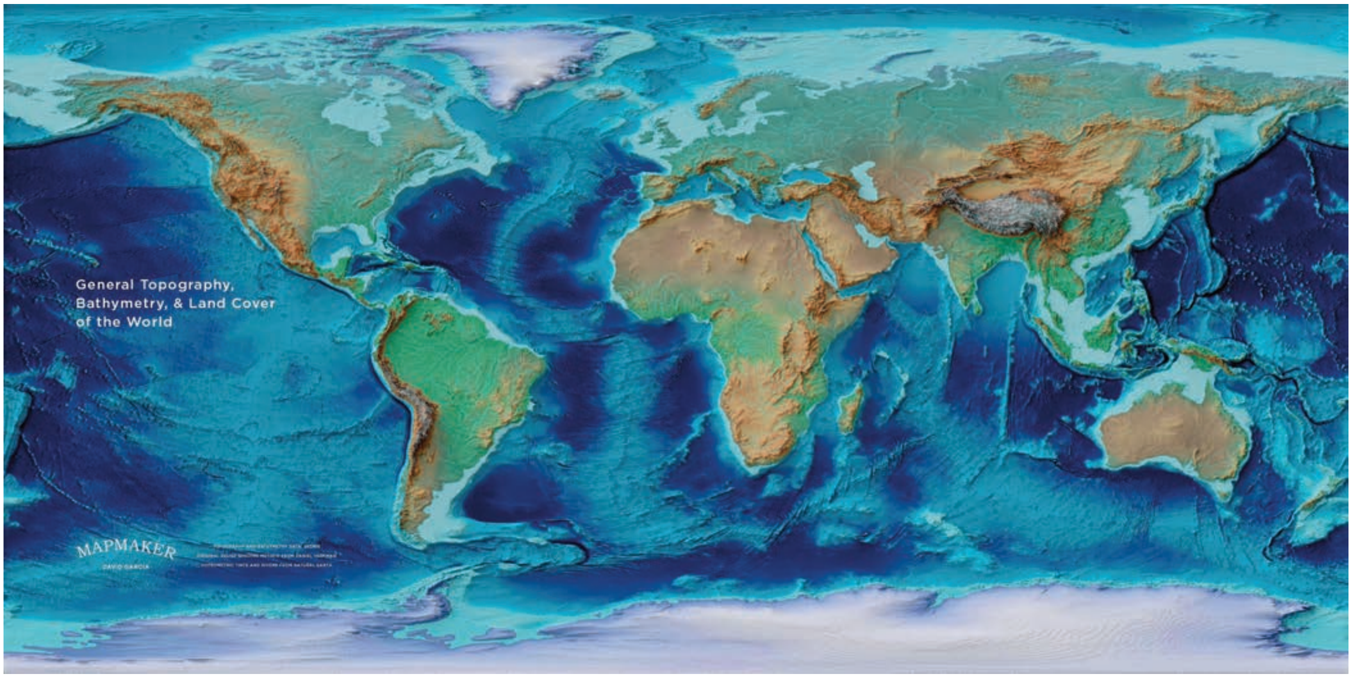

Figure 91-1 Land topography of the surface of the Earth. *(This topographic map is made from data collected from three sources: NASA's Space Shuttle, Canada's Radarsat satellite, and topographic maps made by the U.S. Geological Survey (NASA Earth Observations). Available at neo.sci.gsfc.nasa.gov/view.php?datasetId=SRTM_RAMP2_TOPO.)*

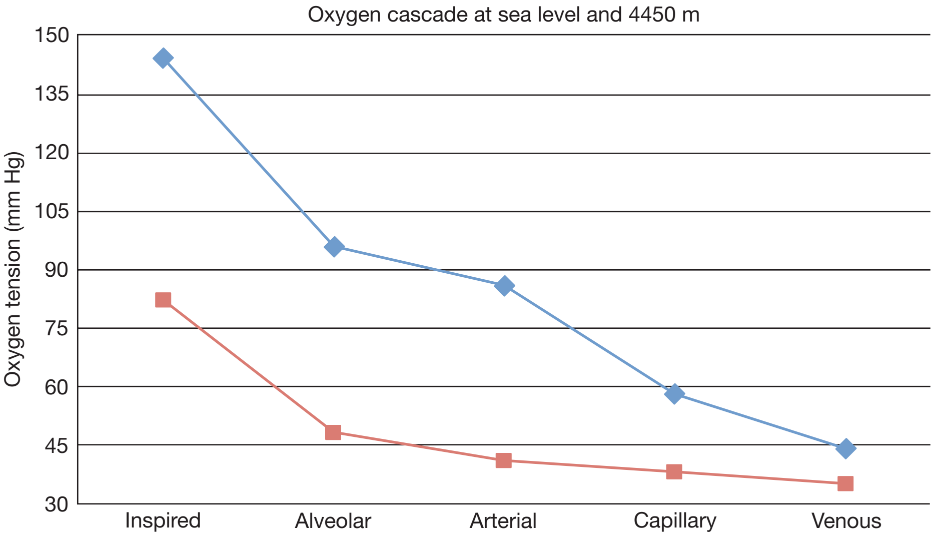

Figure 91-2 Oxygen tension is lower along the axis of oxygen delivery at 4540 m or ~15,000 ft *(red)* compared with sea level *(blue)*.

■ Responses to Hypobaric Hypoxia

The physiologic responses to hypobaric hypoxia involve adaptations in many organ systems, as discussed below.

■ Ventilatory Adaptations

An increase in ventilation is an immediate, vital, mammalian response. It results in a decrease in alveolar CO_2 in order to increase PA_{O_2}, thus mitigating decreases in vascular oxygen delivery at altitude compared with sea level (Fig. 91-2).

The sensor initiating the acute response is the carotid body, located at the bifurcation of the internal and external carotid arteries. Ablation of the carotid body attenuates the acute response to altitude exposure.[12] Blood flowing through the carotid body comes from the lungs via the carotid artery, where the oxygen pressure is typically 80 to 100 mm Hg. Carotid body afferent activity rises significantly as arterial oxygen pressure falls below 60 mm Hg.[12] However, oxygen pressure in the mitochondria is much lower, as oxygen has to diffuse across vessels and interstitial spaces and is extracted by cells for a number of metabolic processes.

In the microvessels of the carotid body, the average oxygen pressure is about 50 mm Hg with minimal values likely near 20 mm Hg. It is reasonable to expect an average mitochondrial oxygen pressure of about 40 mm Hg and a minimum of about 15 mm Hg. Although these values may seem low, in the liver and spleen average tissue values are measured at <12 to 15 mm Hg.[13] Thus, interstitial tissue in the carotid body may be exposed to a lower oxygen pressure than arterial oxygen pressure, which is typically about 80 mm Hg (Fig. 91-3).

The oxygen level is a major driver of carotid body response. Respiration is stimulated by decreasing the [ATP]/[ADP][Pi] ratio; as a result, the rate of respiration does not decrease until oxygen saturation is severe enough (~40 mm Hg) to produce central hypoxic depression leading to gasping, cardiorespiratory failure, and death.[13] At a cellular metabolic level, a sublethal decrease in availability of oxygen first affects the ability of mitochondria to maintain the ratio of [ATP]/[ADP][Pi], which is a measure of energy available when ATP is hydrolyzed to adenosine diphosphate (ADP) and inorganic phosphate (Pi). Mitochondrial ATP synthesis is tightly coupled to oxygen consumption—that is, mitochondria respire only fast enough to replenish ATP as it is used. However, other responses to lowered oxygen levels are engaged depending on the duration and severity of the oxygen deprivation. A slow downward trend in oxygen triggers a fall in cellular and organismal oxygen consumption, and cellular oxygen-sensor responses activate short- and long-term energy savings and cellular protection mechanisms.[14]

A remodeling of ventilatory control begins soon after acute exposure through changes in gene expression. In blood vessels, growth factors such as vascular endothelial growth factor (VEGF) are produced (Fig. 91-4). The exemplary pathway for such responses is mediated by the hypoxia-inducible transcription factor 1 alpha (HIF-1α). HIF-1α is the oxygen-dependent subunit of the HIF-1 heterodimer, considered the master regulator of oxygen homeostasis that initiates transcription of more than 100 hypoxia-inducible genes that have hypoxia-response elements.[15,16] Under normoxia, HIF-1α is formed continuously and degraded in the cytoplasm. HIF-1α is hydroxylated by enzyme prolyl hydroxylases (PHDs) prior to its degradation. The prolyl hydroxylases have a relatively high Km for oxygen; hydroxylation leads to degradation under physiologic conditions. Decreased oxygen pressure results in significant accumulation of HIF-1α in less than 2 min; HIF-1α is rapidly degraded upon reoxygenation.

Central controllers of ventilatory neuromuscular output can be affected directly and indirectly by oxygen availability, but over time, neurotransmitter expression correlates with changes in gain and changes in gene expression, with some additive epigenetic changes.[17] Within days of exposure there is a progressive increase in sensitivity, but there is a downregulation of the magnitude of the ventilatory response by the brainstem networks that integrate afferent information.[18] At 4300 m, hyperventilation increases over the first few days and then over 1 to 2 weeks despite metabolic compensation to the respiratory alkalosis.[19] The acclimatized person continues to hyperventilate when he or she returns to normoxia, a phenomenon not observed during the very first hour of hypoxic exposure. The ventilatory response to chronic hypoxia consists of both respiratory frequency and tidal volume changes. Acclimatized individuals return to nearly normal arterial acid–base status within 24 to 48 h of normoxia following acclimatization to 4300 m.

Hence, a transition occurs from acute to subacute to full acclimatization in the ventilatory domain.[20] Acclimatization is the

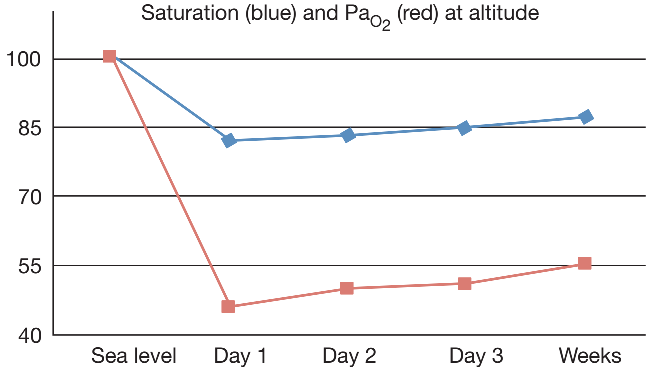

Figure 91-3 The figure illustrates the problem with hypoxemia encountered with acute altitude exposure. Values of arterial oxygen saturation *(blue)* and arterial oxygen tension (Pa_{o_2}, *red*) before, during the first few days at altitude, and after weeks of residence.

physiologic response at cellular and system levels that acts to improve oxygen delivery. Ventilatory responses are complemented by hematologic, cardiovascular, and systemic adaptations. Erythrocytosis and the formation of new blood vessels occurs, reducing the diffusion distance to further assist in increasing oxygen delivery to peripheral tissues. HIF-1α is considered the starting point for activation of "hypoxic response elements" with downstream effects on classic proteins, including erythropoietin.[21] Some actions of erythropoietin result in increases in hemoglobin levels, thereby affecting oxygen-carrying capacity in the blood, an effect that lasts weeks to months. People with a mutation limiting HIF1 degradation have high baseline ventilation and an exaggerated ventilatory response to hypoxia, as well as chronic polycythemia.[22]

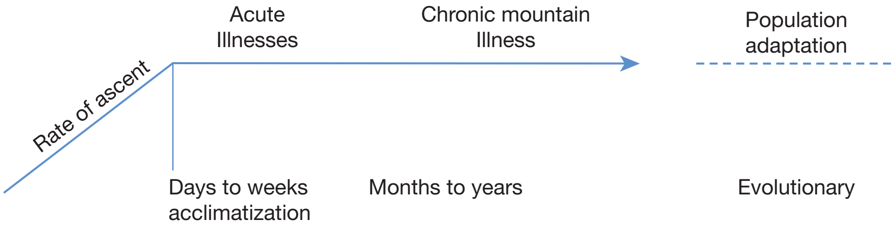

Figure 91-4 Individuals respond to altitude with time-dependent acclimatization and illness expression, and populations living at altitude exhibit adaptations that differ according to population ancestry.

■ Sleep and Periodic Breathing

Healthy persons at altitude experience patterns of regularly recurring periods of hyperpnea and apnea. This phenomenon results from a dynamic interaction among elements in two separate feedback loops—one through peripheral, and another through central, chemoreceptor reflexes, including contributions from changes in cardiac output and brain blood flow.[23] Periodic breathing occurs during wakefulness but is especially evident in sleep, and apneas and hypopnea of the nonobstructive type are reported as occurring almost equally in non-REM and REM sleep in healthy subjects.[24]

Recurrent central apneas occur during sleep at modest altitude (>2000 m) and are a manifestation of increased alveolar ventilation (hyperpnea) from hypoxia producing hypocapnia, and competing with a normal elevation in the apneic (carbon dioxide) threshold during sleep.[25] With increasing altitude, the number of apneic events increases, and hypopneas are often replaced by apneas in healthy individuals.[26] Apneas or hypopneas produce a fall in arterial oxygen and a rise in carbon dioxide that lead to sleep arousals during the hyperpneic phase.[27] The alternating hyperpneas and apneas produce an oscillatory pattern of oxygen saturation, with the nadir of oxygen saturation playing some role in susceptibility to HAPE and HACE.[28]

At altitudes above 3000 m, the quality of both REM and non-REM sleep is impaired by arousals often associated with periodic breathing;[29] at extreme altitude (above 5500 m), the length and number of apneas decrease due to a high frequency of breathing. The reason for this phenomenon may represent a greater relative influence of central oxygen-chemosensitive sites over afferent information than peripheral hypoxia and hypocapnia.[30,31] Fractured and arousal-impaired sleep at altitude may have an effect on cognitive function.[32] With acclimatization, the sleep pattern tends to become more normal; however, periodic breathing during non-REM sleep may persist over a week or more.[28]

■ Pulmonary Circulation

Moderate or severe pulmonary hypertension (both systolic and diastolic) are common in all altitude-related diseases.[3] Although pulmonary blood vessels are extensively supplied with sympathetic (vasoconstrictor) fibers and parasympathetic (vasodilator) fibers, regulation of vasomotor tone is largely due to the local effects of oxygen and carbon dioxide. At altitude, the entire lung is hypoxic and CO_2 levels are low as a consequence of hyperventilation. Indeed, altitude is a model of whole-lung hypoxic, hypocapnic, pulmonary vascular vasoconstrictive responses.[3] Acute vasoconstriction over a few hours is a physiologic response and can be reversed as soon as the hypoxia is reversed. With days to weeks of hypoxic exposure there occur a structural remodeling of pulmonary arterioles and an increase in resting pulmonary arterial pressure and pulmonary vascular resistance; hence pulmonary artery pressure does not decline immediately with restoration of normoxia. With return to sea level after weeks to months, right ventricular hypertrophy and pulmonary vascular pressures return to normal over several weeks.[3]

Andean highlanders have high pulmonary artery pressures and do experience restoration of pulmonary artery pressure or right ventricular hypertrophy to normal levels after inspired oxygen levels are reestablished to normal. In contrast, in a small study, Tibetan highlanders had a minimal elevation of pulmonary artery pressure and did not exhibit the vascular changes seen in the Andean highlanders.[33]

The pulmonary circulation is a high-flow, low-pressure system.[34] Based upon a balance of hydrostatic and oncotic pressure gradients across pulmonary capillary microvessels, and through the action of sodium ion pumps, the pulmonary interstitium and alveolar spaces are maintained in a "dry" state. At high altitude, while respiratory mechanics do not change appreciably, changes in hemodynamics due to vasoconstriction, high shear stress, and vascular injury in certain individuals lead to acute presentations of pulmonary edema.[3,35]

■ Fluid Homeostasis

Dermal edema is seen in the faces of many, but not all, mountaineers at high altitude,[36] and in the retinal vessels of almost all individuals.[37] Lung edema, cerebral edema, and peripheral edema are the hallmarks of disease. Extravasation also may result from loss of tight channels due to oxidative stress and free radicals, or as a direct effect of hypoxia on ion channels.[38] Local dysregulation of the renin-angiotensin-aldosterone system is proposed to play a role in this generalized response.[39,40]

■ Erythropoiesis and Hemoglobin Affinity for Oxygen

An increase in the number of red blood cells occurs with acute altitude exposure owing to an increase in EPO synthesis in response to HIF.[41] This acclimatization response takes between 1 and 3 weeks and is reversible upon return to low altitudes as the "excess" red blood cells die. With chronic hypoxia, increases in the number of erythrocytes and in oxygen content are seen among upward migrants, such as Colorado residents, and among Andean highlanders. Tibetan highlanders have minimal or no erythrocytosis due to the high frequencies of variants in EPAS1 (HIF-2α) associated with a lower hemoglobin concentration.[42–44]

Several studies have assessed the potential for a change in oxygen affinity with altitude. The increase in ventilation with ascent results in decreases in alveolar and arterial PCO_2 and arterial [H^+]; concomitantly, serum levels of 2,3-diphosphoglycerate (2,3-DPG) are increased. While the reductions in Pa_{CO_2} and [H^+] increase hemoglobin affinity for O_2, increases in 2,3-DPG diminish the affinity; loading and unloading of O_2 from hemoglobin depends upon the balance of these factors.[45] Humans native to the Andes or Himalayan mountains may also demonstrate increased O_2 affinity, not because of a fundamental difference in hemoglobin structure or function, but because of extreme hyperventilation and alkalosis; whether this is categorically true has been questioned.[46]

Exercise Physiology and Training

Hypoxic exposure has an been an intriguing subject in studies of physiology of cardiovascular performance and athletic training. The 1968 Mexico City Olympics, which were conducted at 2240 m, highlighted interest in this line of research. On one hand, hypoxia at sea level is known to reduce maximal exercise capacity by reducing oxygen availability;[47] however, exposure to altitude results in an increased red blood cell mass and, therefore, enhances oxygen delivery.

Hemoglobin mass in endurance athletes is not influenced by sea-level training, but it is possible to increase hemoglobin mass temporarily by 5% to 6%, provided that the athlete spends >400 h at altitudes above 2300 to 2500 m. However, this effect size is smaller than the reported 10% to 14% higher hemoglobin values of endurance athletes living permanently at 2600 m.[48] The phrases "train low and sleep high" and "train high and sleep low" both capture the extremes of the conceptual approaches.[49] There are rational effects of different training models currently employed; however, athletes who train high, like others who go to altitude, are susceptible to acclimatization illnesses, weight loss, immune suppression, and sleep disturbances that, if not managed correctly, are likely to limit athletic performance.[50]

In comparisons among exposures, a 3- or 4-week training camp at altitude may initially reduce performance, but after a period of recovery at sea level results in improved performance, even in elite swimmers. Living high and training both high and low for the same period improves swimming performance above and beyond that achieved at altitude and sea level.[51] Studies do not explain the mechanisms involved in training and living at altitude living versus sea level.

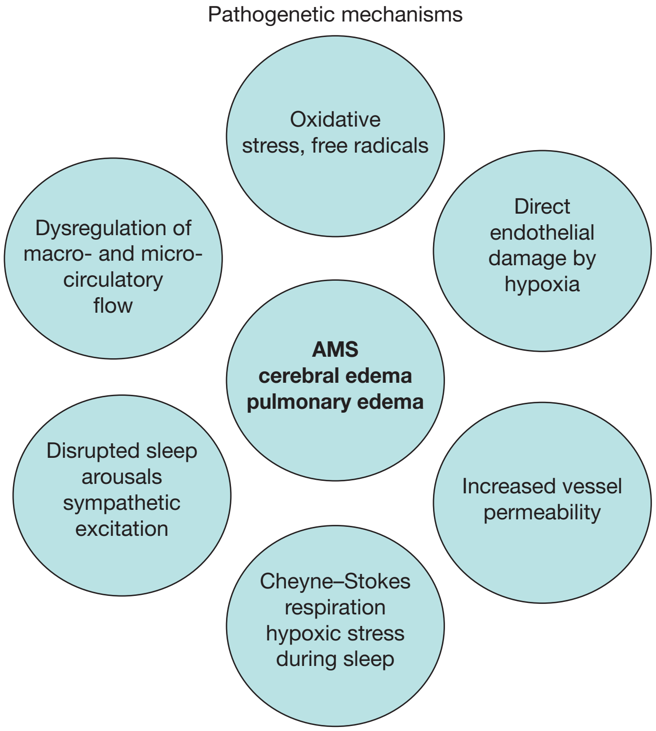
Echocardiographic studies have shown evidence for right ventricular dysfunction and pulmonary hypertension, but no change in left ventricular ejection fraction in training at altitude. Approximately 10% of athletes are susceptible to pulmonary hypertension and high-altitude pulmonary edema.[52] Intermittent training could produce repeated, transient episodes of pulmonary hypertension and right ventricular dysfunction, and the long-term effects are not known. Performance athletes are not at higher risk for ventricular arrhythmias when training or competing at increased altitudes, but persons with preexisting cardia arrhythmia are.[53] At the present time, the "live high, train low" approach appears to have the most traction.[52]

COMMON CLINICAL DISORDERS OF HIGH ALTITUDE

Altitude-related clinical disorders are well recognized. They may be observed occasionally at altitudes as low as 8000 feet (2500 m); however, their frequency increases with increasing altitude. A clinical practice review is available from the Medical Commission of International Mountaineering and Climbing Federation (UIAA).[54] Information about high-altitude travel for those with pulmonary disease also is available.[55]

High-Altitude Headache (HAH)

HAH is very common and is exacerbated by insufficient hydration in the setting of increased water loss with hyperventilation, overexertion, and insufficient energy intake, particularly in those who have experienced HAH on a previous visit to altitude. Vasodilation from hypocapnia also may contribute, but there is little evidence for brain edema in those without neurologic symptoms.[56,57] Acetaminophen or ibuprofen and hydration improve symptoms.[58,59]



Pathogenetic mechanisms
Oxidative stress, free radicals
Direct endothelial damage by hypoxia
Dysregulation of macro- and micro-circulatory flow
AMS cerebral edema pulmonary edema
Disrupted sleep arousals sympathetic excitation
Increased vessel permeability
Cheyne–Stokes respiration hypoxic stress during sleep

Figure 91-5 There is evidence for several mechanisms for AMS, HACE, and HAPE.

Acute Mountain Sickness (AMS)

AMS occurs after 4 to 36 h of altitude exposure. Symptoms include headache (usually frontal), nausea, vomiting, irritability, malaise, insomnia, and poor climbing performance. Symptoms frequently occur initially, or are more severe, the morning after the first night at altitude. Sleep-disordered breathing contributes to the severity of AMS in the morning after the first night at high altitude.[60] AMS is usually self-limited but can be ameliorated by drug therapy (see below).

Many mechanisms have been proposed (Fig. 91-5). Studies target one or another potentially identifiable marker or therapeutic pathway, but few experts believe that only one factor produces one or more of the illnesses.

Incidence

The incidence of AMS is altitude- and time-dependent[61] and is approximately 30% on same-day, several-hour car trips to the Hawaiian or Colorado mountains (3000–4300 m).[7,62] It occurs in 10% of those at 2500 m and 51% at 4500 to 5000 m on multiday trips.[7] A survey of alpine walkers at overnight huts noted an incidence of 9% at 2850 m, 13% at 3050 m, 34% at 3650 m, and 53% at 4559 m.[63] Among trekkers en route to an Everest base camp, the incidence was 43% at 4300 m and was higher in those who had flown into an airstrip at 2800 m (49%) than those who had walked all the way (31%).[64]

The Lake Louise Symptom Score Questionnaire (Table 91-1) is the most common and useful self-administered tool to determine the severity of AMS and provides a score for the five signature symptoms, rating them from 1 (mild) to 4 (severe). A score of 4 and more is considered AMS; a score of 10 and more is considered severe and requires immediate intervention. The Lake Louise Score has recently been revised and excludes in its newest version symptoms of sleeplessness.[65] Copies should be included as equipment of any trekking group to high altitude.[66] Confounders affect such scoring systems; for instance, a hangover will give a positive AMS score even at sea level. Thus, there is a need for context and allowance for

TABLE 91-1 Lake Louise Symptom Score Self-report Questionnaire

Fill out before and each morning upon exposure to altitude or on a trek.

Symptoms	Severity	Points
Headache	• None at all	0
	• Mild headache	1
	• Moderate headache	2
	• Severe headache, incapacitating	3
Gastrointestinal	• Good appetite	0
	• Poor appetite or nausea	1
	• Moderate nausea or vomiting	2
	• Severe nausea or vomiting, incapacitating	3
Fatigue and/or weakness	• Not tired or weak	0
	• Mild fatigue/weakness	1
	• Moderate fatigue/weakness	2
	• Severe fatigue/weakness, incapacitating	3
Dizziness/ lightheadedness	• Not dizzy/lightheaded	0
	• Mild dizziness/lightheadedness	1
		2
		3

Add the responses to each question. A diagnosis of AMS is based on a recent rise in altitude, the presence of a headache with the presence of at least 1 other symptom, and a total score of ≥3 with no evidence for other reason of symptoms.

confounding factors. On the other hand, day-trippers, trekkers, and physicians unaware of the high prevalence of AMS may erroneously assign symptoms and signs to viral illness, food intolerance, poor sleep, intense exercise, or jet lag.

Risk Factors

For novices, the altitude and speed of ascent on a previous trip should be considered, as rapid ascent to altitude appears to affect everybody.[3,66] Women may be less likely to get AMS than men,[67] and there are hints that teenagers and young adults have a higher incidence of AMS as they try to get there first and fastest.[68] Other clinical features reported in the literature include history of migraine, persistence of a patent foramen ovale, Down syndrome, congenital pulmonary abnormalities, perinatal pulmonary vascular insult, and Holmes-Addie syndrome, a rare disorder of autonomic control.[69] Exercise, or at least intense physical effort, does not by itself increase AMS; however, the symptoms of gastrointestinal discomfort are associated with exercise intensity.[70]

Response to challenge with hypoxia improves risk assessment, but it is not routine.[71] A recent report on a fairly large cohort found that factors independently associated with severe high-altitude illness included (1) a previous history of acute illness, (2) ascent greater than 400 m/day, (3) history of migraine, (4) ventilatory response to hypoxia at exercise less than 0.78 L/min, and (5) desaturation at exercise in hypoxia ≥22%.[72] Chemosensitivity parameters (high desaturation and low ventilatory response to hypoxia at exercise) improved discrimination in this prediction model.

While AMS is an environmentally mediated disorder, there are individual differences in risk. The concept is that AMS is a polygenic disorder in which genotype contributes to one's capacity to rapidly and efficiently acclimatize to altitude.[73]

Prevention

Common medical disorders like diabetes, hypertension, mild COPD, hyperlipidemia, mild coronary artery disease, and renal insufficiency are generally not reasons to cancel a trip to high altitude if the same preventive and treatment measures are taken during the travel as they are at home and the traveler is aware of his or her symptoms and how they might change during the trip.[54] Exercise-induced asthma can be anticipated at altitude due to increased ventilation (increased heat exchange), but susceptibility to severe asthma should give one pause in suggesting pleasure trekking, in part because of the lack of medical facilities.[74] Known disease of more than mild severity (COPD, sleep apnea, heart failure, etc.) may be a relative contraindication for travel for pleasure,[55] although there are reports of the successful use of supplemental oxygen for these disorders during ascent. The arterial hypoxemia at high altitude poses a risk of faster disease progression in those with pre-existing kidney disease. An inability to diurese increases the risk of developing acute altitude illness in patients with chronic kidney disease.[75]

Drug interactions require consideration.[58] Acetazolamide is the most widely used pharmacologic intervention for AMS or HACE[1] (Table 91-2). It can cause problems for patients with renal failure (e.g., reduced urine output and increased metabolic acidosis), hepatic insufficiency (ammonium ion toxicity), and COPD (dyspnea) and for pregnant women (accumulating effect with natural higher progesterone levels followed by dyspnea). Patients taking aspirin (acetylsalicylic acid) on a regular basis have reduced acetazolamide elimination and increased central nervous system penetration and toxicity. Use of the phosphodiesterase inhibitors sildenafil and tadalafil should be undertaken with caution because of the danger of serious hypotension in those also treated with nitrates.[38] In one study patients on beta blockers had significantly reduced oxygen saturation and increased cardiac workload with reduced exercise tolerance during hypoxia compared with controls.[76] A change in the antihypertensive drug regimen should be considered.

Pre-acclimatization in a hypobaric chamber has been explored as a way to reduce the risk of altitude illness on a trek or a move to altitude. One study suggested that this may be a useful approach if utilized within a week before the trip.[77] The approach is predicated on a "preconditioning paradigm." However, a recent study suggested that repeated exposure has little effect.[78]

Simple, submaximal exercise testing in an hypoxic environment may be helpful. Exercise tolerance during acute exposure to high altitude can be predicted by a lower individual heart rate response to submaximal exercise assessed at low altitude.[47] Hence, pre-acclimatization could become a method of prevention for the leisure or work traveler, especially those who reach high altitude by plane.

A key element in mitigating altitude-related illness is limiting the rate of ascent to less than 400 m/day.[72,79] A slow rate of ascent is the best way to prevent AMS. A suggested rule is that above 3000 m (10,000 ft), ascent should be at a rate less than 300 m (1000 ft) per day, with a "rest" day (i.e., no additional ascent) every 3 days. This rate will be too fast for some and unnecessarily slow for others.[66] For direct travel to an altitude between 2500 m and 3000 m, the traveler should stay at that altitude for 2 days and then ascend at a rate of 300 m per day.[38] Well-trained individuals ascend too fast and are more vulnerable. The need for acclimatization also implies that those embarking on a "Kilimanjaro in 5 days tour" have no chance for safe acclimatization and are at a high risk for acute altitude illnesses.

An additional rule is, "If symptoms of AMS develop, go no higher. If they become severe, go down." Individuals who ascend to high altitude should be advised to limit their activity for the first few days upon ascent. Adequate hydration should be encouraged, and 2 L of extra fluid per day is a common rule of thumb.

TABLE 91-2 Pharmacologic Therapy for Altitude Illnesses

Syndrome	Medication	Preventive Dose	Therapeutic Dose	Side Effects
Acute mountain illness	Acetazolamide	125 mg at night (adult); 2.5 mg/kg q 12 h (children)	250 mg q 12 h (adult); 2.5 mg/kg q 12 h (children)	Diuresis, paresthesia, metallic taste, nausea, malaise
	Dexamethasone	2 mg q 6 h or 4 mg q 12 h	4 mg q 6 h (oral, IV, or IM)	Hyperglycemia, mood disturbance
	Theophylline	250 mg SR q 12 h		Nausea, headache, drug interactions
	Ibuprofen		400 mg q 8 h	Nausea, GI bleeding
	Acetaminophen		1 g q 8 h	Dose-related liver toxicity
High-altitude headache	Acetaminophen	1 g q 8 h	1 g q 8 h	Dose-related liver toxicity
	Ibuprofen	400 mg q 8 h	400 mg q 8 h	Nausea, GI bleeding
Sleep complaints	Acetazolamide	125 mg qhs x 3 days		Diuresis, paresthesia, metallic taste, nausea, malaise
	Temazepam	5–7.5 mg qhs	5–7.5 mg qhs	Confusional arousals, next-day drowsiness and dizziness
High-altitude pulmonary edema	Nifedipine	30 mg SR q 12 h or 20 mg SR q 8 h	30 mg SR q 12 h or 20 mg SR q 8 h	Dizziness, headache, palpitations
	Dexamethasone	2 mg q 6 h or 4 mg q 12 h		Hyperglycemia, mood disturbance
	Tadalafil	10 mg q 12 h		Dizziness, hypotension, headache, vision disturbance
	Sildenafil	50 mg q 8 h		Dizziness, hypotension, headache, vision disturbance
	Salmeterol	Inhaler 125 μg q 12 h		Tremor, tachycardia; hypokalemia (in African Americans)
High-altitude cerebral edema	Dexamethasone	2 mg q 6 h or 4 mg q 12 h (not indicated for prophylaxis in children)	8 mg once then 4 mg q 6 h (oral, IV, or IM adult); 0.15 mg/kg q 6 h (children)	Hyperglycemia, mood disturbance

Prophylactic administration of acetazolamide is advisable for anyone with a prior history of AMS. Use of acetazolamide (250 mg at bedtime or 125 mg twice daily) for several days after arrival may improve sleep and ability to function during the day. Some suggest starting the drug 2 to 3 days before arrival.[54] Corticosteroids (e.g., dexamethasone at a dose of 4 mg every 6 h) is recommended as an alternative for individuals unable to take acetazolamide (e.g., those with sulfa allergy).[54] The drug is continued for a few days at altitude. In a study of a comparison between acetaminophen and ibuprofen on the incidence of AMS, the drugs were equivalent, despite their different pharmacology. Multifactorial drug effects, that is, anti-inflammatory versus other analgesic mechanisms, appear to be operative.[80] Other therapies either have little support or, at best, supplement this approach.[81]

Treatment

Mild AMS is self-limiting and usually lasts about 3 days, so treatment is not mandatory. A placebo-controlled trial indicated ibuprofen is useful, while the information on aspirin or acetaminophen is anecdotal.[54] If symptoms progress, the traveler should descend (Fig. 91-5). If descent is delayed, acetazolamide is generally considered first-line treatment; dexamethasone can be used in sulfa-allergic individuals. A combination of the two agents can be used for rapidly evolving symptoms. For sleep disturbances, temazepam is effective in reducing recurrent central apnea and arousals and appears to be safe, without any measurable adverse effects the next day.[82] Based on the ability of iron to influence cellular oxygen sensing pathways, one randomized, double-blind, placebo-controlled trial found that intravenous iron supplementation protected against the symptoms of AMS in healthy volunteers.[83] This is, however, impractical for common use.

■ High-Altitude Cerebral Edema (HACE)

If the "mild" edema in the brain worsens toward compression of brain structure, the status of HACE is reached. HACE can occur even in the relative absence of symptoms of AMS.[84] Signature symptoms are dizziness; severe, almost unbearable headache; and vomiting. Ataxia is common;[85] some propose that a positive Romberg sign, the inability to stand straight with the feet together and the eyes closed, is an essential feature.[86] Somnolence, stupor, and changes in pupillary responsiveness mark the onset of a fatal stage. Concurrent signs of pulmonary edema also may be noted. In the absence of treatment, the condition will progress to coma and carries a high mortality.

Descent is critical. While awaiting evacuation, supplemental oxygen should be given. Every 1% increase in oxygen concentration above 21% reduces the equivalent altitude by about 300 m. Several hours in a portable hyperbaric chamber may buy time and be potentially useful as a life-saving measure while descent is arranged;[69] however, the beneficial effects of the portable chamber (Fig. 91-6) may evolve more slowly in HACE than in HAPE, especially in severe cases.[6] Administration of intramuscular dexamethasone (4 to 8 mg) in severe cases, or orally in less severe cases, helps reduce cerebral edema and should be given while awaiting evacuation; doses can be repeated every 6 h.[4]

■ High-Altitude Pulmonary Edema (HAPE)

The typical patient who develops HAPE is a fit young man who has climbed rapidly and is energetic on arrival.[87] Moderate symptoms of AMS may be present initially as the individual becomes more breathless (Fig. 91-5). A cough develops, which is initially dry, then productive of frothy white sputum, later becoming blood tinged. The climber may complain of chest discomfort. The pulse and respiratory rate are increased, and auscultation of the chest reveals crackles at the bases. An elevated jugular venous pressure and peripheral edema may be seen, and a right ventricular heave and accentuated pulmonary component of the second heart sound may be detected. Over a few hours, the patient's condition may deteriorate further, with additional increases in pulse and respiratory rate. As breathing becomes "bubbly" due to pulmonary edema, cyanosis develops. In the absence of definitive treatment, hypoxemia progresses to respiratory failure, and coma and death ensue.

HAPE may occur independently of AMS. The symptoms are like those of pulmonary edema at sea level. HAPE requires a substantial medical intervention (see below). Prevalence estimates are 0.5% to 2.0% of those rapidly ascending to altitude. Individuals with a previous history of HAPE are at greater risk of all altitude-related disorders.[3,4] Some demonstrate a "threshold" effect in which repeated ascents to a particular altitude are associated with development of HAPE, but lower altitudes are not. Individuals residing at high altitude who descend and then return to high altitude are susceptible.

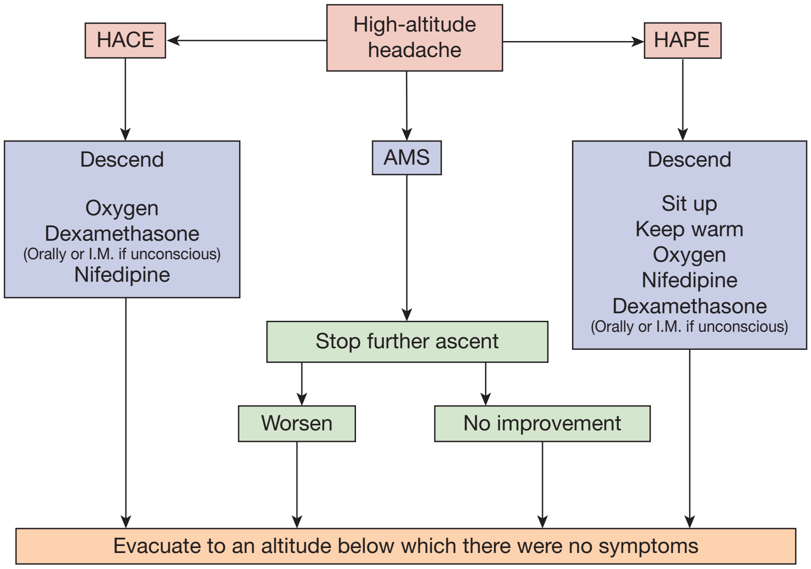


Figure 91-6 Overview of the pathway for management of acute altitude illnesses.

Mechanism

HAPE is caused by migration of fluid into extravasal space through endothelial damage along with shear stresses produced by increased cardiac output and pulmonary artery pressure. The most popular hypothesis is that susceptible subjects experience a hypoxic pulmonary artery vasoconstrictor response that is uneven throughout the lung.[4] In some areas, where there is a greater degree of vasoconstriction, blood flow is reduced, and the areas are protected from development of pulmonary edema. In those areas in which vasoconstriction is less marked, increased blood flow is associated with edema formation, perhaps through flow-related capillary damage, or sheer stress on vessel walls, increased intracapillary pressure, or oxygen radical formation in regions of the lung where blood flow is uneven. In addition, various kinins that have been identified in the edema fluid are likely to increase permeability and to recruit leukocytes.[55]

Prevention

In those who have experienced HAPE previously, use of nifedipine prophylactically (slow-release formulation, 20 mg twice daily prior to ascent, then three times daily) appears to lower significantly the incidence of HAPE.[4,69] Mean systolic pulmonary artery pressure is lowered with this approach, suggesting effects on smooth muscle relaxation. The drug appears to be ineffective in preventing AMS. Prophylactic use of an inhaled beta agonist may reduce the risk of HAPE.[54,55]

Treatment

Descent is critical for survival. Initial medical treatment while the subject awaits descent includes strict rest and supplemental oxygen (Fig. 91-6). Although not yet studied in a well-controlled trial, nifedipine (10 mg sublingually) may be used. If clinically significant hypotension does not occur with the first dose of nifedipine, its administration can be repeated every 15 to 30 min.[4,69] The phosphodiesterase inhibitors sildenafil and tadalafil are becoming fashionable drugs in the treatment of HAPE,[38] but a consensus of efficacy is not available.[4,69] There is a report of the use of nitric oxide and oxygen for this condition.[88] Anecdotally, there appear to be beneficial effects from use of a portable hyperbaric chamber[6] or positive pressure delivered via helmet,[89] constituting temporary measures while descent is arranged.

■ Chronic Mountain Sickness (CMS)

In the 1920s, Carlos Monge reported cases of polycythemia in high-altitude residents of the Andes (Monge disease), and in 1942, Hurtado published detailed observations of eight cases, including symptomatology and hematologic changes.[90] The defining feature is occurrence in a previously well-adapted, asymptomatic high-altitude resident of dyspnea and extreme polycythemia, with hemoglobin concentrations as high as 23 g/dL and hematocrits as high as 83%. Patients may have vague neuropsychological complaints, including headache, dizziness, somnolence, fatigue, difficulty in concentration, and loss of mental acuity. Irritability, depression, and even hallucinations are reported. Dyspnea on exertion is not common, but poor exercise tolerance is. The condition of chronic mountain sickness (CMS) is quite different from AMS.[91] Excessive erythrocytosis associated with a lower oxygen saturation and hypoxic ventilatory response with relative hypercapnia are the main features of CMS, followed by right ventricular enlargement, pulmonary hypertension, and remodeling of pulmonary arterioles.

Risk Factors

Age, sex, and obesity are risk factors in Andean, but not Tibetan, populations. In an ecologic study of 108 Chinese highland military units stationed in Tibet for months to years, the rate of CMS ranged from ∼1% to ∼37% and was higher among rural construction units or those with poorer medical facilities.[92] CMS is more common in males, and in civilian populations it may develop in middle and later life.[90] There may be some risk to children born at altitude with low birth weight for age or whose mothers had problematic pregnancies.[93]

Residence at sea level is the definitive treatment. However, for those who wish to remain at altitude for family or economic reasons, phlebotomy and administration of supplemental oxygen are beneficial.[90] Phlebotomy improves many of the neuropsychological symptoms, and in some patients, pulmonary gas exchange and exercise performance also are improved.

The foundation underlying therapeutic agents for CMS, as well as the clinical evidence that exist to date on their usefulness in the treatment of CMS, is sparse, compared with the work on acute illness.[90] In the Andes, ACE inhibition can effectively and safely ameliorate altitude polycythemia, while also reducing proteinuria.[94] Literature exists on respiratory stimulants, but the studies are not rigorous. Medroxyprogesterone has been employed with some success; side effects, including loss of libido, limit its use.[90] Although acetazolamide has been used in prevention of acute mountain sickness, trials addressing its use in CMS are lacking. However, the drug may be useful in improving oxygen saturation during sleep and, by this mechanism, reducing hematocrit. Further studies are necessary in establishing the role, if any, of sildenafil and related compounds, as well as phlebotomy, in patients with CMS, as used in acute illnesses.

■ Disorders of Altitude Residence

Pulmonary arterial hypertension may develop over months to years of residence at altitude. There is an interesting literature on susceptibility factors. One line of research has identified genetic polymorphisms in the ACE pathway associated with increased hypoxic responses and/or development of pulmonary hypertension.[95] Another line of work has focused on receptor functions, in particular a downregulation in the function of the β-adrenergic receptor system, found in populations at altitude but not at sea level (e.g., pulmonary hypertension in the setting of mitral stenosis).[96] A third invokes a series of dysfunctions in vascular regulation.[97] A fourth may involve a perinatal predisposition for development of high-altitude chronic illnesses in a way that some adult chronic diseases at sea level also have perinatal origins.

An intriguing publication suggested that gestational age, preterm birth, preeclampsia in the mother, or a diagnosis of neonatal hypoxia and impaired growth in utero raise susceptibility to adult disease through a reduced fetal growth of pulmonary vessels and/or an epigenetic effect of perinatal hypoxia.[93] Medications (phosphodiesterase inhibitors and prostaglandins) have been shown to alter pulmonary artery pressures in those born at high altitude and susceptible to pulmonary hypertension, but most of these studies are in smaller groups in a single population.[98–101]

Studies in permanent residents suggest that altitude may aggravate complications of pregnancy and prenatal life. Examples include fetal growth retardation and an increased incidence of the complications of pre-eclampsia and neonatal hyperbilirubinemia, the last noted in Colorado.[102] Mechanisms are not well understood, and interventions in this population have not been performed.[103] Presumably, measures such as prenatal care, vitamin supplements, attention to birth weight, and identification of known risk factors can be implemented in these populations, which often do not appear in Western, lowland health systems.

■ Preparation of Individuals with Cardiopulmonary Comorbidities for High Altitude

The lungs constitute an interface between the atmosphere and the lungs, which provide for oxygen uptake and delivery to the cells and mitochondria.[104] In COPD, ventilatory–perfusion mismatch results in impaired pulmonary gas exchange during wakefulness at sea level that worsens with altitude. For instance, eight patients with COPD and an average FEV_1 of 1.27 L were brought to 1920 m; the Pa_{O_2} fell from a sea-level average of 66 mm Hg to 54 mm Hg within 3 h of arrival at altitude.[105] The lowered oxygenation in patients with COPD poses a possible additional risk for acute mountain sickness.[106] Emphysematous bullae are a low risk for expansion with ascent to altitude, in contradistinction to their risk of expansion with ascent during scuba diving.[107] Interestingly, high altitude may have positive respiratory training effects in patients with COPD, but only if there is a short time of exposure to hypoxic conditions. Respiratory muscle strength also may improve, and it has been suggested that functional improvements in nonventilated lung areas may be seen.[108] Notably, while living at high altitude may have a harmful effect on patients with COPD, there may be a protective effect in ischemic heart disease, resulting in no net effect on anticipated life expectancy.[109]

Patients with COPD whose baseline FEV_1 is <1.5 L should be assessed prior to high-altitude travel to determine the need for supplemental oxygen. Since data suggest that the resting sea-level Pa_{O_2} alone fails to identify a significant number of patients whose Pa_{O_2} falls to 50–55 mm Hg at high altitude, prediction of the Pa_{O_2} at altitude should be based on the regression equation of Dillard: $Pa_{O_2}Alt = 0.519 \times (Pa_{O_2}SL) + 11.85 \times (FEV_1) - 1.76$, where $Pa_{O_2}Alt$ is the Pa_{O2} at altitude and $Pa_{O_2}SL$ is the Pa_{O_2} at sea level. Subjects with a predicted Pa_{O_2} of 50–55 mm Hg should travel to high altitude with supplemental oxygen.[55,110]

Management of patients with COPD at altitude is informed by very few studies. In one study, during travel to 1650 m and 2590 m, those with moderate to severe COPD experienced a mild reduction in exercise performance; however, about 25% of patients subsequently required supplemental oxygen or descent to lower altitude because of adverse health effects.[111] Another study addressed sleep-induced deterioration in gas exchange. In this randomized controlled trial, in lowlanders with COPD in Central Asia travelling to a high altitude, preventive treatment with dexamethasone improved nocturnal oxygen saturation, sleep apnea, and subjective sleep quality.[112]

For patients with asthma, changes of well-being and clinical symptoms at high altitude are inconsistent. Allergic asthma symptoms may decrease because of the lower allergen burden. House dust mites do not exist at altitudes above 2000 m, and concentrations of several classic allergens, like birch pollen, are significantly decreased.[113–115] However, in contrast to symptom improvement related to reduced allergen exposure, hypoxia and reduced air density requiring a higher minute ventilation may worsen respiratory symptoms in asthma. Furthermore, hypoxia constricts airways and increases airway hyperresponsiveness.[116,117] Dry, cold air and increased ventilation may cause exercise-induced asthma, even in those without such a history at sea level, where air is warmer and has higher humidity; the additive effects of intense exercise and "thin" air may well uncover airway hyperresponsiveness.[118]

Despite these pathophysiologic concerns, patients with mild to moderate persistent asthma have successfully travelled to altitudes up to 5000 m. They should be advised to carry a reserve of their regular inhalers, as well as oral prednisone. An additional recommendation is that asthmatics use a peak flow meter to monitor measurements each morning and evening, preemptively increasing therapy if a large drop from evening to morning values is observed. Of course, the absolute value of the measurements is not reliable in the less-dense air at altitude, so changes in measurements over time are the important measurements.

Patients with obstructive, mixed, and central sleep apnea seem to have a significantly increased number of events upon ascent to moderately high altitudes.[30,119] It is reasoned that hypoxia increases the gain of the system to produce recurrent apneas, and as the oxygen saturation is already low, there is a more prolonged and deeper oxygen desaturation. Collapse of the upper airway is more likely to occur in the low-drive portion of the periodic breathing cycle and produce obstructive and hypopneic events. Thus, snorers and patients with diagnosed sleep apnea are likely to experience symptoms.[59]

Patients with sleep apnea should use their Auto-CPAP (Self-adjusting Continuous Positive Airway Pressure) or ASV (Assisted

Servo Ventilation) devices at moderate to high altitude. If PAP treatment is not possible at certain locations, patients should take acetazolamide. Use of acetazolamide has been proven better than no sleep apnea treatment at all.[119]

Those with, or at high risk for, cardiovascular disease need preventive measures for high-altitude sojourns. Because arterial blood pressure and heart rate rise at high altitude and stay increased for at least 7 days after arrival, without nocturnal dipping, the effects provide an additional cardiovascular stress.[120] Pulmonary vasoconstriction in hypoxia stresses the right ventricle, and hypoxia alone can lead to left ventricle alterations. Despite such concerns, the European Society of Cardiology states that patients with heart failure up to level NYHA III can safely ascend to altitudes up to 3000 m if they perform only light physical activity.[121] This position is supported by observations that supervised patients with heart failure NYHA II were able, without cardiovascular events, to exercise at almost 3500 m altitude.[122] Hiking to, and at, high altitude also appears to have a positive training effect for patients with cardiovascular diseases by lowering BP by increasing in left ventricle contractility and improving myocardial oxygenation.[123,124]

The physician must carefully balance pros and cons in advising patients with cardiovascular diseases on high-altitude sojourns. Based on the recommendations of the European Society of Cardiology, blood pressure should be well controlled before ascent to altitude.[121] ACE inhibitors and selective beta blockers are preferred over nonselective beta blockers for the treatment of high BP; acetazolamide should be considered as add-on therapy, both as a diuretic and as a way to reduce periodic breathing. Patients with myocardial infarction or prior coronary stenting should wait 12 months after the event or intervention before considering travel to high altitude. However, patients with mild to moderate stable coronary artery disease (CCS, Canadian Heart Society class I–III) may ascend to altitudes of 2500 m with light physical exercise; patients with CCS 1 are allowed to hike up to 4200 m. In patients with high-risk CCS IV, the recommendation is not to ascend to high altitude.

CONCLUSIONS

Altitude illnesses are the result of acute and chronic residence above 2500 m. With a hurried ascent, many healthy people will report a transient headache (high-altitude headache or HAH), and some will develop one of three forms of acute high-altitude illness: acute mountain sickness (AMS) with or without high-altitude headache (HAH), high-altitude cerebral edema (HACE), or high-altitude pulmonary edema (HAPE). In some resident highlanders, chronic mountain sickness (CMS) and right ventricular hypertrophy develop over months to years. Altitude-associated exposure to cold and UV radiation, exercise, trauma, and infection are important considerations and may affect performance; however, the syndromic presentations are primarily due to hypoxemia and its physiologic responses. Rapid descent is first-line, optimal treatment, although there are some medications that might temporize declining health status. These syndromes and their biologic pathways are not well defined, and the actions of drugs currently employed are empiric and do not directly address hypoxemia. As a result, major gaps in our understanding of high-altitude medicine remain.

CHAPTER 92

Diving Physiology and Dysbarism

Christopher E. Winstead-Derlega
Richard E. Moon

INTRODUCTION

Several million people worldwide participate in diving activities, including recreational, commercial, military, and competitive breath-hold diving. This chapter provides an introduction to the physiology of diving and clinical presentations of dysbarism (i.e., medical conditions arising from changes in ambient pressure), as well as an outline of fitness-to-dive principles for medical screening.

THE FIELD OF DIVING

Breath-hold diving was undoubtedly first performed thousands of years ago, and it continues today during international competitions and commercial pearl diving, mostly in the Asia-Pacific region. The maximum depth of breath-hold diving is limited predominantly by the depletion of oxygen and the mechanical effects of pressure on the thoracic contents, as is discussed in more detail below.

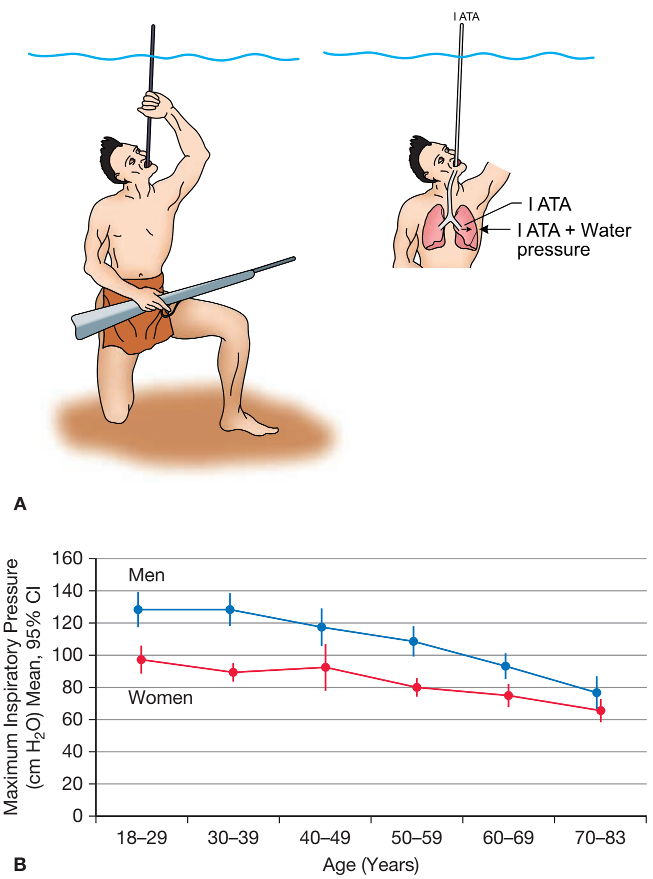

Figure 92-1 Limits of snorkel. **A.** The average adult is limited to a functional depth of 1 m due to limited strength of the inspiratory muscles to overcome the hydrostatic pressure applied to the chest. **B.** Maximum inspiratory pressure in males and females as a function of age. *(Data from Sclauser Pessoa IM, Franco Parreira V, Fregonezi GA, et al. Reference values for maximal inspiratory pressure: a systematic review. Can Respir J. 2014;21(1):43–50.)*

Breathing at shallow depth can be performed using a snorkel; however, the maximum depth is constrained by the degree to which the inspiratory muscles can breathe against the transthoracic pressure imposed by the hydrostatic pressure of the water column. Maximum inspiratory pressure varies with age and sex; for a healthy young adult it is impossible to inhale through a snorkel at depths greater than one meter[1] (Fig. 92-1). Prolonged excursions underwater can, therefore, only be performed by delivering compressed gas to the diver at the ambient pressure of the environment.

In 1942 Jacques Cousteau and Emile Gagnan designed the Aqua-Lung, an open-circuit, self-contained underwater breathing apparatus (SCUBA). With this system, the diver breathes from a regulator that delivers gas at ambient pressure. Breathing gas is stored in pressurized steel or aluminum tanks and is delivered by a series of first- and second-stage regulators, which reduce the gas pressure to the ambient pressure of the diver; exhaled gas is released into the environment.

An alternative technology, developed by naval forces at about the same time, is the closed-circuit rebreather. This device allows the diver to rebreathe expired gas, thus eliminating bubbles, increasing efficiency, and maintaining secrecy. Carbon dioxide is removed by a chemical absorbent, while oxygen is replenished from a pressurized oxygen tank. In the 1940s, rebreathers used 100% oxygen, which was discovered to produce fatal central nervous system oxygen toxicity due to seizures at depths beyond 8 to 9 meters (25–30 ft). Today's rebreathers rely on complex sensors to deliver gas at a desired partial pressure, thus allowing deeper dives. Surface-supplied diving, or hookah diving, allows for an individual diver with an enclosed helmet to be connected to a surface-supplied air source via an umbilical line that carries air, heat, and communication (Fig. 92-2).

During and after surfacing from a dive, excess tissue inert gas (e.g., nitrogen) can form bubbles, causing *decompression sickness* (DCS).[2] DCS symptoms most commonly include joint pain, numbness, paresthesias, and skin rash (Fig. 92-3) but may be more serious with involvement of the spinal cord (motor weakness, paraplegia/quadriplegia), brain (confusion, difficulty concentrating, memory loss), and inner ear (vertigo, hearing loss). Low levels of gas bubbles in the venous blood (venous gas emboli [VGE]) are usually filtered by the pulmonary circulation and may occur after a dive without

symptoms. However, large amounts of VGE can injure the vascular endothelium, causing plasma loss, shock, and pulmonary edema (known as "chokes"). Reduction of DCS risk may require scheduled "stops" during decompression to allow orderly inert gas washout from tissues and off-gassing (Fig. 92-4). Arterial bubbles (arterial gas embolism [AGE]) also can occur due to pulmonary barotrauma (see below). Treatment of both DCS and AGE consists of general supportive measures, supplemental oxygen (even in the absence of hypoxemia), and hyperbaric oxygen.[2–4]

In order to perform underwater tasks at deep depths, such as those needed for commercial purposes, the required decompression time may grossly exceed the time at maximum depth. For such

scenarios, the technique of *saturation diving* is often used, in which a group of divers live in a hyperbaric environment on a dive support vessel and "commute" to work on the ocean floor, usually in pairs, in a pressurized diving bell. After a "shift" they then return to the living environment, at which time two other divers travel to the worksite. Oxygen fraction must be reduced such that the ambient P_{O_2} is not toxic. Tissue inert gas partial pressures are at equilibrium ("saturated") with the environment. To avoid dysbarism, decompression at the end of the time at depth must be performed at a very slow rate (Fig. 92-4).

PHYSIOLOGICAL EFFECTS OF DIVING

Below we consider the wide variety of physiologic effects that occur with diving.

■ Toxic Effects of High Ambient Pressure

Partial pressures of component gases, such as nitrogen and oxygen, increase linearly with ambient pressure and are associated with pharmacologic or toxic effects, including inert gas narcosis and oxygen toxicity. The effects may require an adjustment of the breathing gas mix (Fig. 92-5) or replacement of nitrogen with helium, which has no narcotic effects. Ultra-high pressures (e.g., 15–20 atmospheres absolute, ATA, or greater) can induce a syndrome consisting of nausea, tremor, and ataxia known as *high pressure nervous syndrome* (HPNS).[5]

■ Immersion Effects

Because blood and water have similar densities, the tendency for blood to pool in splanchnic and lower-extremity veins in the upright position due to gravity is eliminated during immersion. As water level rises relative to the body during immersion, there is a progressive tendency for blood to redistribute into the cardiac and pulmonary vessels, which is enhanced in cold water immersion.[6] The resulting engorgement of the central veins, cardiac, and pulmonary vessels causes intravascular pressures, including pulmonary artery wedge pressure, to increase.[7,8] Lung volumes are, therefore, reduced;[9,10] total lung capacity (TLC) typically decreases by 10%, functional residual capacity (FRC) by 50%, and expiratory reserve volume (ERV) by 73% (Fig. 92-6).

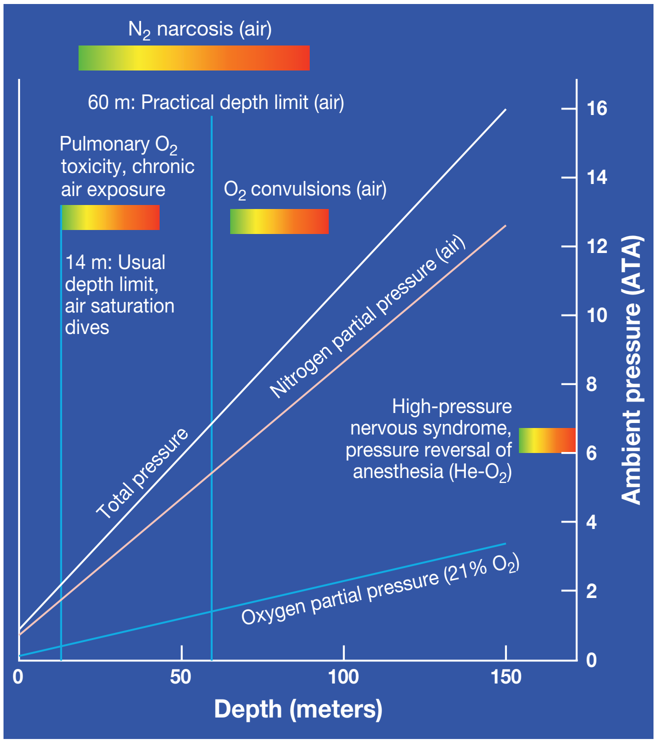

Figure 92-5 Pressure and gas partial pressure as a function of depth. Depicted are depth ranges (green-to-red: increasing severity) while breathing air for occurrence of nitrogen narcosis, pulmonary and central nervous system oxygen toxicity. Depth range for high-pressure nervous syndrome is shown for helium-oxygen breathing. See text for details.

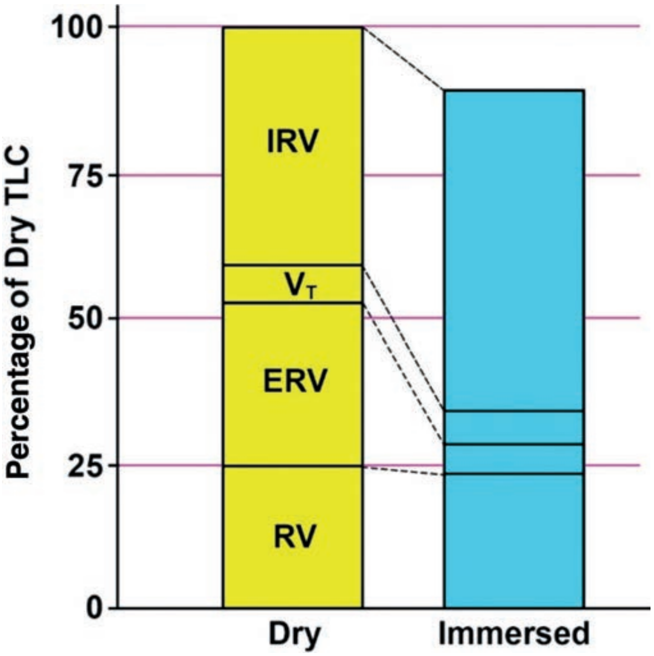

Figure 92-6 Effects of immersion on lung volumes. TLC, FRC, and ERV decrease with immersion, while RV is largely unchanged. These changes are due largely to the shift of intrathoracic blood volumes and compression of the chest wall. *(Data from Agostoni E, Gurtner G, Torri G, et al. Respiratory mechanics during submersion and negative-pressure breathing. J Appl Physiol. 1966;21(1):251–258.)*

■ Mechanical Load

During a dive, mechanical changes occur in load parameters, including *flow resistance*, *lung elastance*, and *respiratory inertance*. Gas density increases linearly with pressure, causing airway resistance to increase, particularly in large airways where turbulent flow occurs.[11] During expiration, collapsing airways can induce flow limitation.[11] These effects cause reductions in forced expiratory volume in 1 s (FEV_1), peak expiratory flow (PEF), and maximum voluntary ventilation (MVV).[12–16] MVV at high gas density (ρ) can be approximated by the following formula:

$$MVV = MVV_0(\rho/\rho_0)^{-k}$$

where MVV_0 is MVV at 1 ATA; ρ is gas density at the ambient pressure of the dive; ρ_0 is gas density at 1 ATA; and k is a constant with the value 0.4 to 0.5. A similar equation has been verified for the relationship between airway conductance and gas density.[17] This relationship becomes important during underwater exertion, where levels of ventilation appropriate to the CO_2 production rate may exceed mechanical limitations of MVV.

In addition to airway resistance, resistive properties in underwater breathing apparatus add to the overall respiratory load. Theoretically, changes in viscosity could affect laminar gas flow patterns in small airways; however, within the pressure range to which humans can be exposed, viscosity is unchanged.

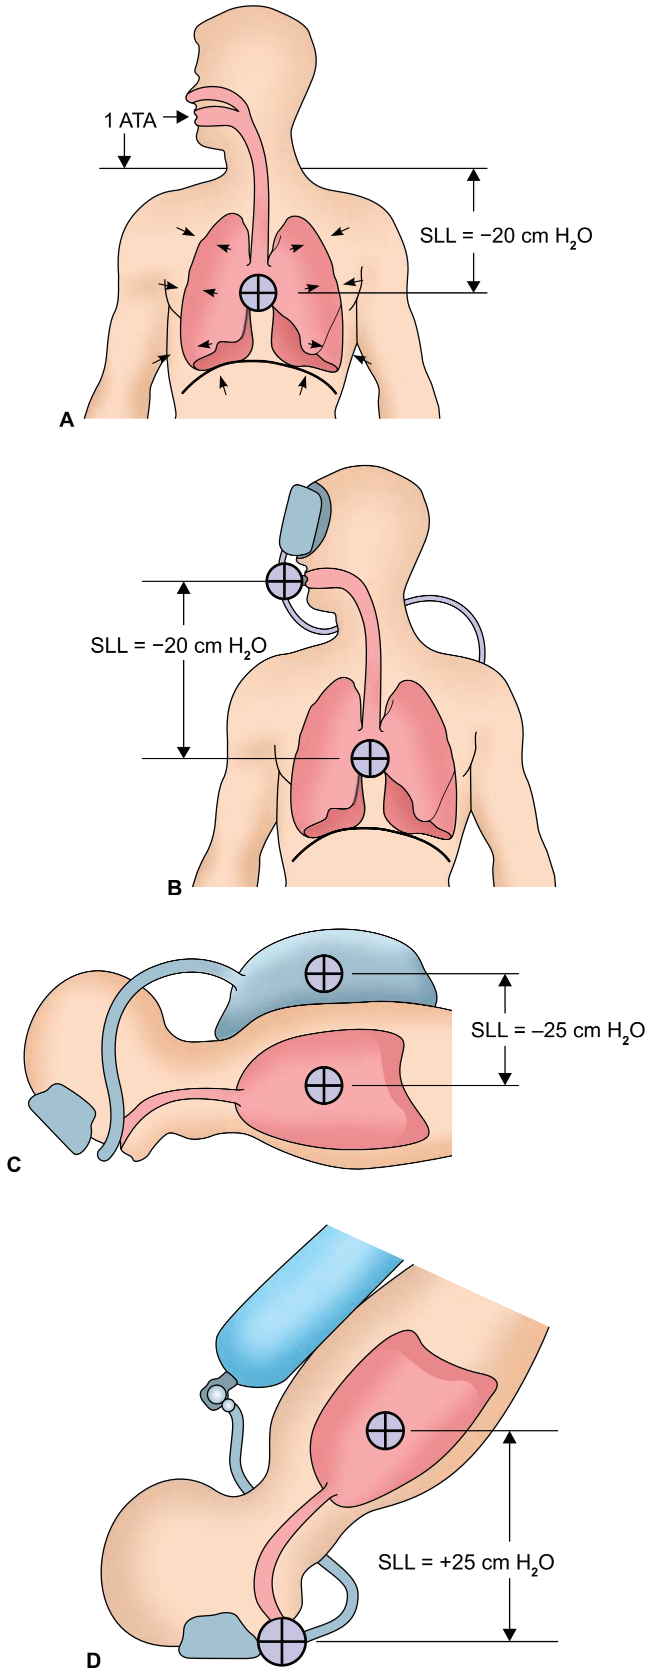

Figure 92-7 Static lung load (SLL), transrespiratory pressure gradient, changes with relative position of the breathing regulator apparatus and lung centroid. The face-down diving position offers divers a positive pressure due to greater ambient pressure at the regulator when compared to the lung. *(Reproduced with permission from Lundgren CE, Miller JN: The Lung at Depth. New York, NY: Marcel Dekker; 1999.)*

Mechanical load during diving may also be affected by thoracic *elastance*. Chest wall compliance does not change; however, redistribution of blood into the thorax and vascular engorgement caused by immersion may increase lung elastance.[18] Differences in hydrostatic pressure between the lung and the mouth (transthoracic pressure) also may increase elastic load[19,20] (Fig. 92-7). The immersion-related increase in elastic load reduces MVV by an additional 10% over that caused by high gas density.[21]

High gas density increases *inertance*, which is the tendency to resist acceleration. Inertance is a function of the mass of the chest wall, the gas flowing within the airways, the breathing apparatus, and, to a minor extent, the water surrounding a diver's torso, which must be accelerated and decelerated with breathing. At 1 ATA respiratory system inertance is typically 0.01 cm $H_2O \cdot L^{-1} \cdot sec^{-2}$, which increases in direct proportion to gas density.[22,23] Due to the normally reduced respiratory rate in divers, inertial impedance affects respiratory effort minimally. In an exercising diver, breathing a gas with a density of 10 $g \cdot L^{-1}$ and assuming a peak acceleration of 30 $L.s^{-2}$, the transrespiratory pressure due to inertance would be only approximately 3 cm H_2O.[24]

The net effect of this increase in mechanical load is relative hypoventilation[25] and hypercapnia.[16,26–31] High external breathing resistance may cause incapacitating CO_2 retention, even without dyspnea or other symptoms.[32,33] The effects of increased mechanical load may also be augmented by inadequate respiratory muscle performance due to poor function or fatigue.

■ Ventilatory Drive

Ventilatory drive (hypercapnic ventilatory response [HCVR]) can be a factor in determining the effect of diving on ventilation and, hence, in determining arterial P_{CO_2}.[30,34–38] While HCVR is mostly an intrinsic phenotypic property, it can be affected by *hyperoxia*, *narcosis*, and *respiratory muscle training* (RMT). Hyperoxia, which is ubiquitous in diving, attenuates the ventilatory response to hypercapnia;[24] however, only extreme values for P_{O_2} in inspired gas (1.75 ATM) have been shown to have even a minimal effect on the increase in P_{CO_2}.[31]

Nitrogen narcosis, via a similar mechanism, could also contribute to hypercapnia during diving. While HCVR is, indeed, attenuated at increased ambient pressure, studies using nonnarcotic gases have demonstrated that the reduction is due to the effect of increased gas density on resistive load.[30,39,40] HCVR varies several-fold within the normal population, and RMT has been reported to have no effect on average HCVR. However, RMT tends to increase the HCVR of those with low C_{O_2} ventilatory response and decrease HCVR of those with high response.[41]

■ Intrapulmonary Gas Exchange

Other factors related to the lung itself may influence both oxygen and carbon dioxide exchange, including *gas mixing and diffusion*, *distributions of blood flow and ventilation*, *ventilation/perfusion* ($\dot{V}_A/\dot{Q}$) *matching*, and *hemoglobin-oxygen affinity*.

Gas Mixing and Diffusion

Mixing of inspired and alveolar gas is determined by *convective mixing* (dependent partly on cardiogenic oscillations), *Taylor dispersion*, and *diffusion*,[42] all of which could be affected by an increase in gas density. Higher gas density promulgates turbulent flow to more distal airways and enhances cardiogenic mixing, thus improving the efficiency of gas exchange.[43] On the other hand, a high gas density could diminish Taylor dispersion (and worsen gas exchange) due to increased turbulent flow and reduce gas phase diffusivity in distal airways and alveoli.[44] While it is not possible to individually assess the effects of these phenomena, the overall effect of diving on pulmonary gas exchange can be assessed by measurement of arterial blood gases, as discussed below.

Distributions of Ventilation, Blood Flow, and $\dot{V}_A/\dot{Q}$

Distribution of ventilation during normal respiration depends on regional mechanical properties of the lung. At normal atmospheric pressure (and breathing gas density) time constants of different lung units are similar; thus, ventilation of different lung regions is reasonably uniform. However, at increased gas density the geometry of the lung is no longer optimal, and heterogeneity of ventilation is increased, leading to more disperse constants and asynchronous ventilation.[24,45,46] If these inequalities of ventilation are appropriately matched by regional changes in perfusion, $\dot{V}_A/\dot{Q}$ matching is preserved. Most studies have shown evidence of impaired CO_2 transport (increased physiologic dead space),[16,27,29,30,47,48] implying impaired pulmonary exchange of CO_2, although immersion appears to attenuate this effect except at extremely high P_{O_2} (1.75 ATA).[49] On the other hand, analysis has suggested that increased breathing gas density improves pulmonary oxygen exchange (i.e., a reduced alveolar–arterial difference, $PA_{O_2} - Pa_{O_2}$) due to promotion of intraregional convective mixing and, hence, reduced $\dot{V}_A/\dot{Q}$ dispersion.[47] Lung perfusion is not temporally uniform but rather varies cyclically with respiration, which may also improve alveolar–pulmonary capillary oxygen exchange.[50,51]

Hemoglobin-Oxygen Affinity

Increased affinity of hemoglobin for oxygen (decreased P_{50}, "shift to the left" in the oxyhemoglobin dissociation curve) has been observed at 50 to 100 ATA in vitro[52–55] and in vivo in humans during a saturation dive to 69 ATA.[56] This effect is most likely due to pressure-induced conformational changes in hemoglobin and, to a lesser extent, inert gas binding. However, small changes in hemoglobin P_{50} of the magnitude described are unlikely to have a significant effect on pulmonary gas exchange or exercise capacity, particularly at common diving depths.[57]

Effect of Diving on Arterial Blood Gases

The net effect of the processes described above has been tested by measurements of arterial blood gases during hyperbaric chamber studies.[16,27–30,49,58,59] Despite mild or moderate hypercapnia during exercise, adequate blood oxygenation occurs at gas densities up to 17g/L[29] and exercise performance (thus presumably oxygenation) at densities up to 25 g/L.[14]

PATHOLOGIC EFFECTS OF DIVING

A number of important pathologic consequences of diving may occur and are discussed in the following sections.

Pulmonary Barotrauma and Arterial Gas Embolism

Pulmonary barotrauma during a dive occurs when the diver ascends at a rate at which intrapulmonary gas expansion due to the reduction in ambient pressure exceeds the rate at which gas is exhaled. This typically occurs during breath-holding, but it can also occur due to regional hyperexpansion secondary to lung pathology, including lung cysts, bullae,[60] and obstructive lung disease.[61]

Lung parenchyma ruptures at transthoracic pressures of 70 to 80 mm Hg (95–108 cm H_2O),[62] which can be generated by a breath-hold ascent from a depth of 1 m. The most common presentation is pneumomediastinum and subcutaneous emphysema; pneumothorax is rare (Fig. 92-8). Gas entry into pulmonary capillaries can result in *arterial gas embolism* (AGE), which most commonly manifests as rapid onset of stroke-like symptoms (motor weakness, confusion, impaired consciousness). AGE can also result from VGE crossing into the systemic circulation via either intrapulmonary or intracardiac shunts.

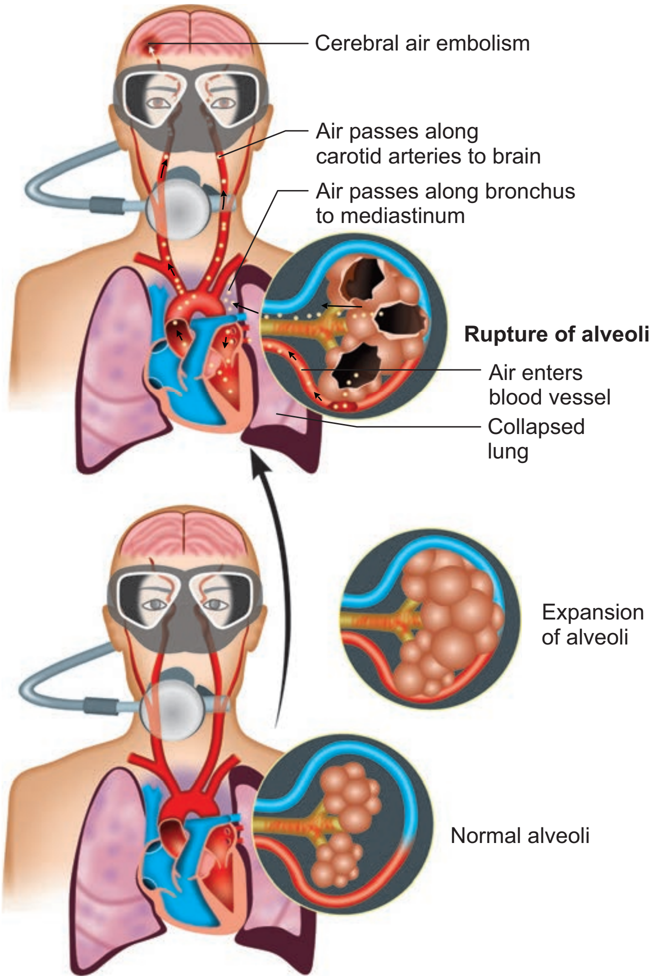

Figure 92-8 Pulmonary barotrauma. Gas trapped in the alveoli expands on ascent. As pressures increase alveoli will rupture and air will enter the mediastinum, pulmonary veins, and arterial circulation. Pneumothorax is rare. Cerebral air embolism can cause loss of consciousness and death.

Impaired Gas Exchange After Saturation Dives

During saturation dives, divers remain in a hyperbaric environment for many days or weeks where they are exposed to higher-than-normal ambient P_{O_2} (typically 0.4–0.5 ATM). During this time they may experience mild lung toxicity, in addition to the pulmonary effects of prolonged low-level venous gas embolism during decompression, which often lasts several days. After a saturation dive to 37 ATA, divers have reduced $\dot{V}O_{2max}$ and carbon monoxide transfer factor and increased respiratory dead space.[63–65]

Immersion Pulmonary Edema

Immersion pulmonary edema (IPE, often termed *swimming-induced pulmonary edema* [SIPE]) is a condition in which cough, hemoptysis, dyspnea, and hypoxemia develop after surface swimming or diving, often in young, healthy individuals,[66–68] including exceptionally fit military divers, triathletes, and other competitive swimmers.[69] Risk factors include cold water, older age, female sex, nonsteroidal anti-inflammatory drug (NSAID) use, depth of dive greater than 20 m, physical exertion, and hypertension. Left ventricular dysfunction,[70–72] including Takotsubo cardiomyopathy,[73–75] also is a risk factor.

Invasive studies during submersed exercise in individuals with a history of SIPE have revealed higher than normal pulmonary artery and pulmonary artery wedge pressures, consistent with hemodynamic pulmonary edema.[76] Pre-swim sildenafil administration may reduce the risk of SIPE;[76,77] however, for divers breathing hyperoxic mixtures (P_{O_2} >1 ATM), sildenafil may increase the risk of CNS oxygen toxicity and seizures underwater.[78]

The diagnosis of SIPE can be made on clinical grounds with, in addition to the manifestations listed above, typical pulmonary signs. It is notable that the distribution of fluid is predominantly anterior, and physical examination reveals abnormal lung sounds predominantly over the anterior chest.[69,79] Fatal cases have been reported,[80–83] although the condition usually resolves spontaneously after removal of the patient from the water, which immediately reverses the hemodynamic conditions that produced pulmonary edema. General supportive measures may be appropriate, including administration of supplemental oxygen and aerosolized β-adrenergic agonists. Diuretic therapy is rarely required.

Gas Toxicity

Nitrogen narcosis, or "rapture of the deep," is the intoxicating effect of breathing inert compressed nitrogen gas.[84] Narcotic effects are similar to those of alcohol intoxication (the "Martini effect"); symptoms are progressive and are initially seen at a depth of around 30 m. Narcosis may present with changes in behavior, memory, and cognition. These effects are quickly reversed by ascending to shallower depths. While some divers report a pleasurable effect of nitrogen narcosis, it can lead to diving error, injury, and subsequent death.

Breathing oxygen at oxygen partial pressures greater than 1.4 to 1.6 ATM places divers at risk for central nervous system oxygen toxicity. Symptoms are of sudden onset and include headache, twitching, nausea, tinnitus, and seizures. Donald's early studies in navy divers set a limit to diving on 100% O_2, concluding that dives below 8 m (25 ft) are dangerous and potentially fatal if a seizure were to occur during submersion.[85] Various mitigation strategies for CNS oxygen toxicity, including ketone diets and antiepileptic medications, are being researched.

Pulmonary oxygen toxicity occurs more gradually, with a rate that is dependent on the $P_{O_2,}$ and demonstrates a more consistent dose–response relationship. At P_{O_2} values greater than 0.5 to 0.6 ATM, tracheobronchitis (causing burning chest pain) and then pulmonary edema develop, for which a reduction in vital capacity has been used as a marker.[85,86] These changes are usually reversible when P_{O_2} is promptly reduced to normal.

Toxicities of contaminant gases, such as carbon monoxide, are also related to their partial pressures. Thus, subtoxic concentrations of contaminants at sea level pressure may become toxic during a dive.

BREATH-HOLD DIVING

Unlike SCUBA divers who breathe compressed gases at ambient pressures, breath-hold divers explore the undersea environment on a single breath of air. For thousands of years, coastal communities have employed this technique for sustenance hunting and food collection. Modern Ama, or "sea-women," in Korea and Japan continue to practice breath-hold diving as a commercial occupation. Over the last decade, competitive breath-hold diving, or "free diving," has provided venues for extreme pulmonary physiology research.[87] The deepest dive in no-limits free diving was made by Herbert Nitsch (214 m or 702 ft) in 2007.

The breath-hold diver experiences lung compression in direct relation to the increase in ambient pressure. When TLC is reduced to residual volume, the additional lung volume reduction induced by further descent is accomplished by blood redistribution into the pulmonary vessels. However, once pulmonary capillaries reach their elastic limit, additional descent can result in rupture, hemoptysis, and pulmonary edema.[88] Fatal cases of arterial gas embolism after shallow breath-hold dives are reported due to entry of gas into disrupted pulmonary capillaries.[89]

Initial lung volume (and, hence, deepest dive depth) is often increased beyond TLC pre-dive by competitive breath-hold divers by "lung packing" via glossopharyngeal insufflation. Elite divers can raise their vital capacities to 114% to 181% of predicted values,[90] which transiently decreases lung compliance.[90] Transpulmonary pressures of 43 to 80 cm H_2O have been observed in breath-hold divers practicing glossopharyngeal insufflation.[90] Glossopharyngeal insufflation allows for larger volumes of air in the lungs and chest, effectively extending dive times. This practice impedes venous return and cardiac preload, and may lead to loss of consciousness and, in one case reported, pneumomediastinum.[90]

Pre-dive behaviors alter the diver's physiologic state and dampen hypoxia signals. Hyperventilating or "pre-breathing" is common. Breath-hold divers increase minute ventilation to reduce levels of carbon dioxide.[91] The elevated pH of the blood causes a left shift in the oxygen hemoglobin dissociation curve, which favors oxygen binding. The mechanism of shallow water blackout involves a diminished hypercapnic triggered urge to breathe, while succumbing to cerebral hypoxia (Fig. 92-9).

Alveolar gas partial pressures increase as the diver descends in the water column. The highest partial pressures of oxygen are predicted to be at maximum depth. Bosco et al. demonstrated this in a breath-hold diving study in which arterial blood samples were obtained at maximum depth during a 40-m breath-hold dive.[92] Interestingly, two of six divers demonstrated a lower P_{O_2} than predicted, which was thought to be due to alveolar collapse and right-to-left intrapulmonary shunting due to atelectasis[96] (Fig. 92-10). Hypoxia of ascent occurs as a result of the diver's metabolic consumption of oxygen and a reduction of partial pressure of oxygen during surfacing. As the breath-hold diver approaches the surface, the oxygen partial pressure can drop below the level required to sustain consciousness. Compared with P_{O_2}, changes in P_{CO_2} are much less due to the higher solubility of carbon dioxide, allowing changes in P_{CO_2} to be buffered within plasma and extravascular water.

FITNESS-TO-DIVE ASSESSMENT

According to the Sports and Fitness Industry Association, there are an estimated 2.4 million recreational SCUBA divers in the United States[93] who are required to complete a medical screening form

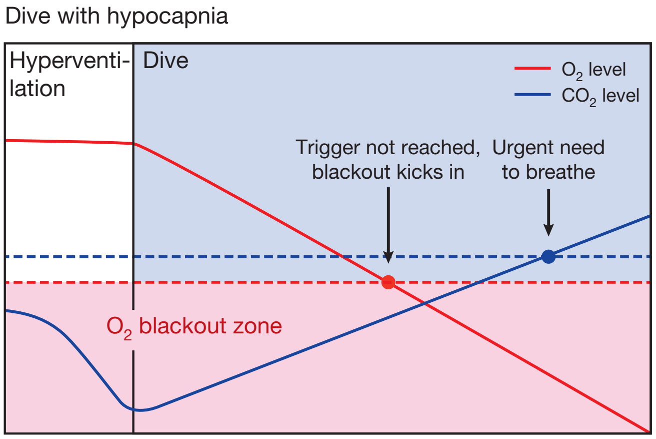

Figure 92-9 Oxygen and carbon dioxide levels in blood during a breath-hold dive. The dashed blue line represents the arterial P_{CO_2} level at which there is an urgent need to breathe; the dashed red line is the oxygen saturation at which loss of consciousness (LOC) occurs. During breath-holding, P_{CO_2} rises and blood oxygen saturation falls. Generally the urge to breathe occurs before LOC. However, if the diver hyperventilates before the breath-hold the urge to breathe is delayed and LOC may then be the initial event, causing drowning. Red line, O_2 saturation; blue line, Pa_{CO_2}.

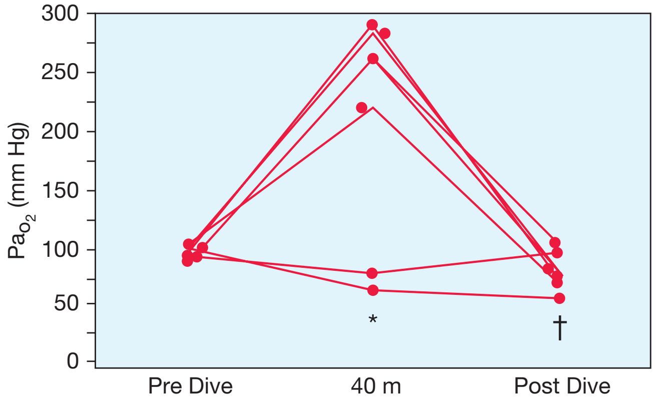

Figure 92-10 Pa_{O_2} in the breath-hold diver. Individual Pa_{O_2} measurements before, at maximum depth (40 m), and after a breath-hold dive. For the majority of divers, Pa_{O_2} increased with depth. $^{*}p < 0.05$ vs. pre-dive; $^{\dagger}p < 0.05$ vs. 40 m. *(Reproduced with permission from Bosco G, Rizzato A, Martani L, et al. Arterial Blood Gas Analysis in Breath-Hold Divers at Depth. Front Physiol. 2018;9:1558.)*

prior to participation. A preexisting condition may require consultation with a physician, preferably one with diving medicine expertise. Employed divers or volunteer divers working for a scientific or public health organization are required to complete more rigorous medical screening, a physical examination, and testing prior to clearance.[94]

Pulmonary conditions, such as bullae, lung cysts, chronic obstructive pulmonary disease, asthma, lung scarring, and pulmonary fibrosis can cause air trapping and pulmonary barotrauma during ascent. Pulmonary barotrauma may cause pneumothorax, air embolism, and/or pneumomediastinum. A history of spontaneous pneumothorax is an absolute contraindication to diving activity, as recurrence is common and unpredictable.[95]

Diving-related conditions that may exacerbate or strain preexisting pulmonary pathology also need to be taken into account, including effects of cold dry air, increased airway resistance, increased gas density, regulator breathing resistance, and heavy exertion. For individuals with a history of asthma, a consensus panel[96] recommended that fitness to dive should include absence of asthma-related symptoms, normal spirometry, and absence of airways hyperreactivity on a provocation test (later formalized by the American Thoracic Society to consist of exercise breathing dry air).[97] Mild asthma can often be controlled with inhaled corticosteroids such that these criteria can be met. Studies have documented up to 12% of divers with airflow obstruction on spirometry without apparent ill effect.[98] Nevertheless, documented instances of arterial gas embolism after shallow dives in asthmatic patients indicate some degree of risk.[61] Therefore, it is prudent for asthmatic divers to avoid diving when symptomatic, and the conservative approach outlined above is most likely the safest.

Appropriate pulmonary screening in asymptomatic patients for anatomic anomalies is controversial. Pulmonary structural abnormalities, including cysts or bullae, can lead to air trapping and alveolar barotrauma.[99] Inspiratory and expiratory CT scans with volumetric image acquisition can detect subtle gas trapping in high-risk individuals, although expiratory CT scans can demonstrate gas trapping in patients with normal lungs.[100]

Radiologic screening for lung anomalies in all divers is impractical and costly and will reveal incidental findings that are unlikely to pose additional risks. Commercial divers, given their frequent exposure and commercial liability, require initial and routine chest radiograph.[94] The limitations of chest radiograph were demonstrated in a cohort of 101 military divers undergoing screening with both plain chest radiograph and high-resolution computed tomography (HRCT).[101] Chest radiographs in 7 of the 101 divers (7%) detected bullae or blebs. Follow-up HRCT failed to identify pathology in 3 of the 7 positive studies.[101] Of the 94 divers with normal chest radiographs, 7 (7%) had bullae or blebs and 23 (24%) had other pulmonary or extrapulmonary findings; findings on HRCT were disqualifying in half of the cases.[101] The authors concluded that a routine screening chest radiograph is not reliable in asymptomatic patients; furthermore, while HRCT increases sensitivity, it detects anomalies that may lead to undue disqualification.[101] For divers who wish to return to diving after chest wall trauma, intrathoracic surgery, or traumatic pneumothorax, HRCT and pulmonary spirometry are usually performed.

For divers previously infected by COVID-19, return-to-dive guidelines have been developed, with examinations focused on cardiac and pulmonary function and exercise tolerance.[102]

FITNESS FOR HYPERBARIC EXPOSURE ASSESSMENT

Similar to divers, patients and attendants of hyperbaric chambers require fitness-to-dive assessments. Hyperbaric oxygen therapy centers treat a variety of specific indications.[103] Hyperbaric physicians, and physicians referring to these centers, should review patient medical histories, as certain medical conditions, implanted devices, and pharmaceutical therapies are contraindications for hyperbaric oxygen exposure. Pulmonary barotrauma is rare in hyperbaric chambers, likely due to the absence of immersion physiology effects and slow controlled decompressions. Patients with lung conditions that may be disqualifying for diving can usually safely complete hyperbaric chamber therapy, although a patient with severe cystic lung disease experienced pulmonary barotrauma and fatal cerebral and cardiac gas embolism after a hyperbaric treatment following 19 previous uneventful treatments in a hyperbaric chamber.[104] Such instances are extremely rare; however, radiographic imaging is recommended for individuals with clinical lung disease.

Chamber attendants are repetitively exposed to hyperbaric environments. Occupational safety and health concerns related to increased ambient pressure and fire risk are unique;[105] attendants require similar fitness-to-dive assessments. Pulmonary pathologies leading to air trapping are disqualifying.[106] Occupational exposures to dysbarism pathologies are rare, although DCS and otic barotrauma are reported.[107]

CONCLUSION

Decompression illness occurs in only a small number of divers but is an international problem that few physicians are trained to recognize or manage. Although its manifestations are often mild, the potential for permanent injury exists in severe cases, especially if unrecognized or inadequately treated. Emergency medical personnel should be aware of manifestations of decompression illness in the setting of a patient with a history of recent diving or other exposure to substantial pressure change and should contact an appropriate consultation service for advice.[108]

Divers and diving-related illness are relatively few in number, although there is a constant need for physicians to evaluate individuals wishing to participate in either recreational or professional diving. Physicians should be aware of the signs and symptoms of pulmonary barotrauma, arterial gas embolism, and decompression sickness and should be prepared to administer urgent first aid and refer patients for definitive care as rapidly as possible. Immersion pulmonary edema appears to be increasingly common, and physicians should be aware of how to evaluate subsequent risk in patients with a suggestive history.

CHAPTER 93

Thermal Lung Injury and Acute Smoke Inhalation

Perenlei Enkhbaatar

INTRODUCTION AND EPIDEMIOLOGY

Smoke inhalation is a serious medical problem and continues to have a significant impact on the morbidity and mortality of patients with flame burns. According to the American Burn Association repository, inhalation injury is one of the most lethal characteristics of burn patients, and its presence is associated with an overall mortality rate of 20% between 2009 and 2018; mortality is only 2.9% in those patients without smoke inhalation.[1] Inhalation injury is present in 17% of patients with flame burns,[2] and its presence prolongs the length of hospital stay 2.5-fold compared to those without smoke inhalation injury (24 days vs. 10 days).[2]

Similar percentages of fire victims who have sustained smoke inhalation appear in several other countries.[3–6] In patients with combined injury, the lung is the critical organ, and the progressive respiratory failure associated with pulmonary edema is a pivotal determinant of mortality.[7–9] Although not as lethal, smoke inhalation alone is a serious problem. It is estimated by the World Health Organization that there are more than one billion people who develop airway and pulmonary inflammation as a result of inhaling smoke from indoor cooking fires, forest fires, and burning of crops.[10,11]

The inhalation of smoke has been of interest for a number of years, especially as the result of the use of gas warfare. In the 1940s there were two very large fires that focused interest on the inhalation of smoke in fire victims. The first was a fire at a nightclub in Boston called the Cocoanut Grove, where a large number of people were trapped in a burning building and consequently sustained severe inhalation injury.[12,13] It is interesting that in recent times a similar fire occurred in a nightclub near Boston in Rhode Island. The second occurred in Texas City across the bay from Galveston, Texas.[14] Here a ship exploded in a harbor and set off a chain of explosions and fires among some 50 refineries and chemical plants, resulting in more than 2000 hospital admissions of patients with smoke inhalation alone, as well as those with burn injuries, many of whom who had simultaneously inhaled smoke as well. These two disasters led to the establishment of centers for the care of burn victims and to research into the pathophysiology of burn injury. In many ways, the burn victims of the 9/11 disaster were similar to these individuals since the burns and inhalation involved combustion of petroleum products.[15,16] Approximately half (49%) of 790 victims who survived the World Trade Center attack had an inhalation injury.[16,17]

THE FIRE ENVIRONMENT: TOXIC SMOKE COMPOUNDS

Inhalation injury is caused by steam or toxic inhalants such as fumes, gases, and mists. Fumes consist of small particles dispersed in air with various irritants or cytotoxic chemicals adherent to the particles. Mists consist of aerosolized irritant or cytotoxic liquids. Smoke consists of a combination of fumes, gases, mists, and hot air. Heat, toxic gases, and low oxygen levels are the most common causes of death in a fire scene. A large variety of toxic gases and chemicals can be generated depending on the fire environment (Table 93-1).

Many of these compounds may act together to increase mortality—especially carbon monoxide and hydrogen cyanide,[18,19] for which a synergism has been found to increase tissue hypoxia and acidosis[19] and, perhaps, decrease cerebral oxygen consumption and metabolism.[20,21] Hydrogen sulfide would also be predicted to synergize with carbon monoxide since both cyanide and hydrogen sulfide are inhibitors of mitochondrial cytochrome oxidase. Victims may be incapacitated by the blinding and irritating effects of smoke, as well the decreasing oxygen concentration that occurs with combustion and results in progressive hypoxia.

Inhalation injury can be classified as follows: (1) upper airway injury, (2) lower airways and pulmonary parenchymal injury, and (3) systemic toxicity.

The extent of inhalation damage depends on fire environment: the ignition source, temperature, concentration, and solubility of the toxic gases generated. For instance, thermal and chemical compounds usually cause upper airway injury. The water-soluble materials, such as acrolein and the other aldehydes, damage the proximal airways and set off reactions that are inflammatory to the bronchi and parenchyma, whereas agents with lower water solubility such as chlorine, phosgene, nitrogen oxide, and nitrogen dioxide or N_2O_3, or even N_2O_4, are more likely to cause insidious injury.[22] Toxic gases such as carbon monoxide and cyanide rarely damage the airway but affect gas exchange, producing more systemic effects. Thus, it is important to obtain information relative to the source of the fire and the combustion products generated when treating a fire victim (Table 93-1). It is also important to know the duration of exposure and the extent to which the fire victim was in an enclosed area because this relates to the dose of toxic materials presented.

■ Carbon Monoxide

Carbon monoxide (CO) is an odorless, colorless gas that is produced by incomplete combustion of many fuels, especially cellulolytic (cellulose products) such as wood, paper, and cotton.[23] Carbon monoxide toxicity remains one of the most frequent immediate causes of death following smoke-induced inhalation injury. There are 50,000 estimated annual visits to emergency departments in the United States as result of CO poisoning.[24] The predominant toxic effect of CO is its binding to hemoglobin to form carboxyhemoglobin (COHb). The affinity of CO for hemoglobin is ~200 to 250 times higher than that of oxygen.[25] Inhalation of a 0.1% CO mixture may result in generation of a COHb level as high as 50%. The correlation of inhaled CO and COHb levels is summarized in Table 93-2.

Competitive binding of CO to hemoglobin reduces delivery of oxygen to tissues, leading to severe hypoxia, especially of the most vulnerable organs such as brain and heart. The oxygen–hemoglobin dissociation curve loses its sigmoid shape and is shifted to the left, thus further impairing tissue oxygen availability.[18] In addition, ability of CO to bind to intracellular cytochromes and to other metalloproteins contributes to CO toxicity. This competitive inhibition with cytochrome oxidase enzyme systems (most notably, cytochromes a and P-450) results in an inability of cellular systems to use oxygen.[28] Shimazu et al. have shown that extravascular binding of CO to cytochromes and other structures accounts for 10% to 15% of total body CO stores, which explains the two-compartment elimination of CO from the circulation.[29] CO also inhibits cytochrome c oxidase activity in lymphocytes. The electron chain dysfunction by CO may cause electron leakage, leading to superoxide production and mitochondrial oxidative stress. Additionally, excessive nitric oxide (and its byproduct peroxynitrite), lipid peroxidation, apoptosis, and delayed inflammation[30–33] contribute to CO toxicity at both systemic and cellular levels.

■ Symptoms and Diagnosis

The symptoms predominantly manifest in organs and systems with high oxygen utilization. The severity of clinical manifestations is

TABLE 93-1 Origin of Selected Toxic Compounds

Gases and Chemicals	Material	Source
Carbon monoxide	Polyvinyl chloride	Upholstery, wire/pipe coating, wall, floor, furniture coverings Clothing, fabric
	Cellulose	Wood, paper, cotton
Cyanide	Wool, silk	Clothing, fabric, blankets, furniture
	Polyurethane	Insulation, upholstery material
	Polyacrylonitrile	Appliances, engineering, plastics
	Polyamide	Carpeting, clothing
	Melamine resins	Household and kitchen goods
Hydrogen chloride	Polyvinyl chloride	Upholstery, wire/pipe coating, wall, floor, furniture coverings
	Polyester	Clothing, fabric
Phosgene	Polyvinyl chloride	Upholstery, wire/pipe coating, wall, floor, furniture coverings
Ammonia	Wool, silk	Clothing, fabric, blankets, furniture
	Polyurethane	Insulation, upholstery material
	Polyamide	Carpeting, clothing
	Melamine resins	Household and kitchen goods
Sulfur dioxide	Rubber	Tires
Hydrogen sulfide	Wool, silk	Clothing, fabric, blankets, furniture
Acrolein	Cellulose	Wood, paper, cotton, jute
	Polypropylene	Upholstery, carpeting
	Acrylics	Aircraft windows, textiles, wall coverings
Formaldehyde	Melamine resins	Household and kitchen goods
Isocyanates	Polyurethane	Insulation, upholstery material
Acrylonitriles	Polyurethane	Insulation, upholstery material

Reproduced with permission from Prien T, Traber DL. Toxic smoke compounds and inhalation injury–a review. Burns Incl Therm Inj. 1988;14(6):451–460.

varied depending on the concentration of CO. For instance, the central nervous system symptoms such as headache, confusion, and collapse may occur when the blood COHb level is 40% to 50%. Symptoms such as unconsciousness, intermittent convulsions, and respiratory failure may occur if the COHb level exceeds 60%, eventually leading to death if exposure continues. The cardiovascular manifestations result in tachycardia, increase in cardiac output, dysrhythmias, myocardial ischemia, and hypotension, depending on the severity of poisoning. The correlations of clinical manifestations and severity of CO poisoning are summarized in Table 93-3.[34,35]

Blumenthal et al. correlated the clinical signs and symptoms of CO poisoning with the concentration of inhaled CO: headache,

TABLE 93-2 COHb Levels at Various Concentrations of Inhaled CO[26,27]

CO in Atmosphere		Estimated Carboxyhemoglobin in Blood (%)
%	ppm	
0.001	10	2
0.007	70	10
0.012	120	20
0.022	220	30
0.035–0.052	350–520	40–50
0.08–0.122	800–1220	60–70
0.195	1950	80

TABLE 93-3 Symptoms and Signs at Various Concentrations of COHb

COHb %	Symptoms
0–10	None
10–20	Tightness over forehead, slight headache dilation of cutaneous blood vessels
20–30	Headache and throbbing in the temples
30–40	Severe headache, weakness, dizziness, dimness of vision, nausea, vomiting
40–50	As above; greater possibility of syncope, increased pulse and respiratory rate
50–60	Syncope, increased pulse and respiratory rate, coma, intermittent convulsions, Cheyne–Stokes respirations
60–70	Coma, intermittent convulsions, depressed cardiac and respiratory function, possible death
70–80	Weak pulse, slow respirations, death within hours
80–90	Death in less than one hour
90–100	Death within minutes

Reproduced with permission from Einhorn IN: Physiological and toxicological aspects of smoke produced during the combustion of polymeric materials. Environ Health Perspect. 1975;11:163–189.

dizziness—up to 100 ppm, 0.01% air concentration; loss of judgment, confusion, disorientation—up to 200 ppm, 0.02%; and nausea, vomiting, fatigue, confusion, disorientation, visual disturbance, and syncope, up to the onset of coma—800 ppm, 0.08% to 12,800 ppm, 1.28%.[36]

Diagnosis should be based on direct measurement of COHb levels in arterial or venous blood by co-oximetry. Portable breath analyzers may be used at the scene. Inability to differentiate oxyhemoglobin from COHb limits the use of pulse oximeters. Although there are some controversies on its reliability, fingertip pulse CO oximetry, a technology available since 2005, can be used at the scene of the fire for measurement of COHb.[37] The use of blood gas analyzers that estimate SO_2 based on measurement of dissolved PO_2 should be avoided. The measurements of acid–base balance, plasma lactate levels, and bicarbonate are helpful in management of CO poisoning with accompanying lactic or metabolic acidosis. It is important to note that high oxygen concentrations are usually administered to the victim in transit to the hospital, and some delay from cessation of exposure to measurement of CO may limit evaluation of the true extent of exposure.[38] A nomogram has been developed that relates the COHb levels of a patient to the values that may have been present at the time of smoke inhalation; this tool can be used to estimate the true degree of inhalation injury.[39]

■ Treatment

The half-life of COHb is 320 min (adult male) in room air and ~74 min in a person breathing normobaric 100% oxygen at 1 atmosphere.[40,41] These values are 30% shorter in females.[42] Therefore, all fire victims should be isolated from the fire site and given 100% oxygen en route to the hospital. Oxygen inhalation via face mask allows delivery of an inspired oxygen concentration of 50% to 60%, which is usually adequate.

To adequately treat a CO poisoning it is important also to establish COHb level as early as possible. In patients with loss of consciousness, cyanosis, or an inability to maintain the airway, 100% oxygen should be delivered via mechanical ventilation through endotracheal tube until COHb levels drop below 10% to 15%. The alternative method to rapidly decrease COHb is hyperbaric oxygen therapy (HBOT). HBOT allows CO to dissociate from cytochrome a and a3 and to increase PO_2 despite impaired hemoglobin function.[43,44] Chou et al. reported that children with CO poisoning alone who are treated with HBOT are at low risk for dying regardless of initial COHb level.[45] However, there is some debate on use of HBOT, especially in patients with burn injury. Because of the difficulty of physiologic monitoring and providing emergency procedures in small chambers, unstable hemodynamic conditions, and other complications such as seizures or aspiration of severely burned patients, the use of hyperbaric oxygen therapy is limited.[46] In severe cases, extracorporeal membrane oxygenation (ECMO) may be considered. McCunn et al. published a case report on the use of ECMO; they noted immediate reduction in the level of COHb, as well as improved oxygenation. Cardiovascular failure was reversed.[47]

Additionally, the use of pharmacologic antidotes may be of interest for efficient disassociation and elimination of CO. Some agents have been tested in preclinical studies. Roderique et al. reported that combined hydroxocobalamin and ascorbic acid efficiently converted CO to CO_2, thus reducing COHb half-life time from 33 min to 17.5 min.[48] In another study, Kitagishi et al. reported that an O_2-bound form of an iron(II) porphyrin, cyclodextrin supramolecular complex, captured CO and promoted excretion in the urine.[49] However, efficacy and safety of these agents should be further investigated to be translated to clinical practice.

■ Hydrogen Cyanide

Hydrogen cyanide is a colorless gas with the odor of bitter almonds. However, it is difficult to detect it at the site of the fire. Cyanide is a likely weapon for terrorists because of its notoriety, lethality, and availability. Hydrogen cyanide is produced in fires involving nitrogen-containing polymers (upholstery, furniture, nylon, wool, silk, and acrylics) and may produce rapid and lethal incapacitation of a victim at the fire source.[50]

Toxicity of cyanide is produced by inhibition of cellular oxygenation with resultant tissue anoxia, which is caused by reversible inhibition of cytochrome c oxidase.[51] It is toxic to a number of enzyme systems. The mechanism includes combination with essential metal ions, formation of cyanohydrins with carbonyl compounds, and sequestration of sulfur as thiocyanate. However, the main target enzyme is cytochrome c oxidase, the terminal oxidase of the respiratory chain, and involves interaction with the ferric ion of cytochrome a_3.

■ Symptoms and Diagnosis

Diagnosis at the fire scene may be difficult. Poisoning leads to central nervous system, respiratory, and cardiovascular dysfunctions resulting from inhibition of oxidative phosphorylation and may result in dyspnea, tachypnea, vomiting, bradycardia, hypotension, coma, and seizures. Electrocardiographic S-T segment elevation, which mimics an acute myocardial infarction, may be suggestive.[52] Laboratory findings of anion gap metabolic acidosis and lactic acidemia aid in confirming the diagnosis.[51] A lactic acidosis that is not rapidly responsive to oxygen therapy may be a good indicator of cyanide poisoning.[39,53] Also, an elevated mixed venous saturation is suggestive of cyanide toxicity. Cyanide increases ventilation through the carotid body by increasing peripheral chemoreceptor stimulation. Increasing ventilation may augment toxicity in the early stages. Correlations of blood cyanide concentrations with clinical symptoms are summarized in Table 93-4.[34,54]

Hydrogen cyanide is found routinely in low levels in the blood of healthy individuals (0.02 μg/mL in nonsmokers and 0.04 μg/mL in smokers). Toxicity occurs at a level of 0.1 μg/mL, and at 1.0 μg/mL death is likely.[55]

■ Treatment

Fire victims suspected to have cyanide poisoning should be removed from exposure and fully decontaminated. All victims should be

TABLE 93-4 Hydrogen Cyanide Concentrations in Air and Associated Symptoms in Humans

HCN Concentration ppm	Symptoms
0.2–5.0	Threshold of odor
10 (maximum allowed concentration)	Mild irritation of mucus membranes
18–36	Slight symptoms (headache) after several hours, irritation of throat
45–54	Tolerated for 0.5–1 h without difficulty of breathing
100	Death in 1 h
110–135	Fatal in 0.5–1 h
181	Fatal in 10 min
280	Immediately fatal

Aspects and methodology for the evaluation of toxicological parameters during fire exposure. In: Polymer Conference Series: Flammability Characteristics of Materials. Salt Lake City, UT: University of Utah; 1973.

given pure oxygen (100%) and resuscitated properly if cardiopulmonary failure is present. Oxygen therapy appears to have strong beneficial effect; however, hyperbaric oxygen therapy is not recommended for the reasons previously mentioned.[51,55]

Cyanide is metabolized by hepatic rhodanese, which catalyzes the donation of sulfur from the sulfane pool to cyanide to form nontoxic thiocyanate. The half-life time of cyanide is approximately 1 to 3 h in humans.[43,56] Although there is still controversy surrounding the treatment of cyanide poisoning, there are few antidotes available that can be used by first responders. Kelocyanor (dicobalt edetate) may be useful, but is dangerous and requires experts to administer it.[57] The following agents may be considered in an intensive care setting.

Methemoglobin Generators

The therapeutic goal is to convert the ferrous ion of hemoglobin to ferric ion. The resultant methemoglobin chelates cyanide to form cyanmethemoglobin. (Cyanide has a greater affinity for binding with methemoglobin and thus is displaced from cytochrome oxidase.) The drugs of choice in this group are sodium nitrite (intravenously) and amyl nitrite (inhaled). These drugs reduce oxygen-carrying capacity; therefore, they should be used with caution, especially in patients with concomitant CO poisoning which induces COHb that may further compromise oxygen transport. These drugs should be also used with precautions in patients with shock, because they are also vasodilators and can cause hypotension. In addition, there is little evidence to suggest these measures are effective, and cardiac toxicity in people with heart disease may be problematic.[58] Thus, the methemoglobin generators should be used with extra precautions, carefully weighing patient conditions and comorbidities.

Sulfur Donors

The therapeutic goal is to convert cyanide to thiocyanate. The drug of choice in this group is sodium thiosulfate (administered intravenously). Toxicity is minimal, other than an osmotic diuretic action, which may be beneficial. However, the onset of action is quite slow. Therefore, it should be used as a second-line therapy.[18,59]

Direct Binding Agents

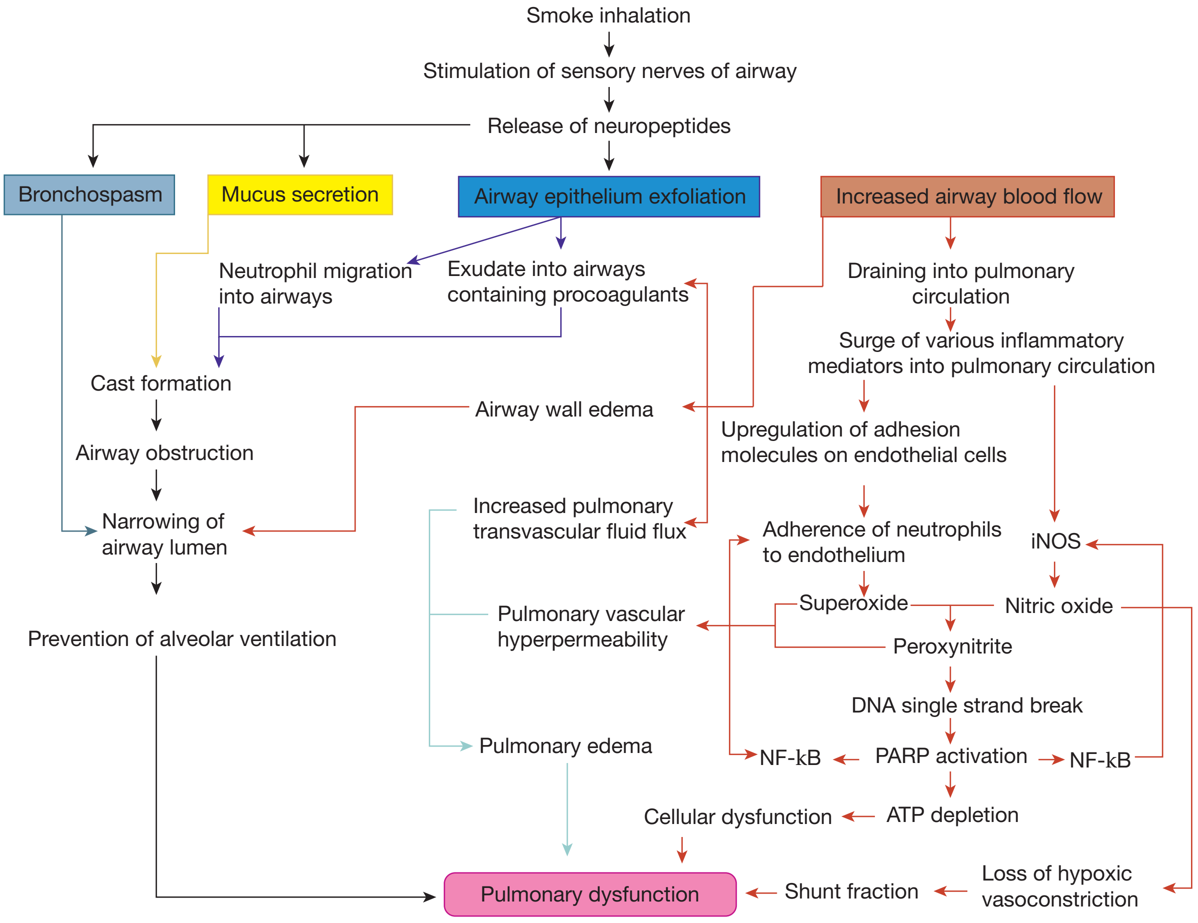
These are based on cobalt chemistry and chelate the cyanide ion directly. Hydroxocobalamin is the precursor of vitamin B_{12} and has very little toxicity.[18,55] Minor adverse effects include transient chromaturia, alterations in renal function, reddish skin discoloration, hypertension, and, rarely, allergic reactions.[60,61] The agent detoxifies cyanide by binding with it and forming cyanocobalamin, which is then excreted in the urine. The drug is currently approved for use by the U.S. Food and Drug Administration (FDA). However, there is controversy around its efficacy.

PATHOPHYSIOLOGY

Below we consider thermal injuries to the tracheobronchial tree and the lung parenchyma.

Tracheobronchial Tree

In normal conditions, the airway provides a protective barrier against toxic agents and bacteria, maintaining a sterile lung environment.



Smoke inhalation
Stimulation of sensory nerves of airway
Release of neuropeptides
Bronchospasm
Mucus secretion
Airway epithelium exfoliation
Increased airway blood flow
Neutrophil migration into airways
Exudate into airways containing procoagulants
Draining into pulmonary circulation
Surge of various inflammatory mediators into pulmonary circulation
Cast formation
Airway wall edema
Upregulation of adhesion molecules on endothelial cells
Airway obstruction
Narrowing of airway lumen
Increased pulmonary transvascular fluid flux
Adherence of neutrophils to endothelium
iNOS
Superoxide
Nitric oxide
Prevention of alveolar ventilation
Pulmonary vascular hyperpermeability
Peroxynitrite
DNA single strand break
Pulmonary edema
NF-kB
PARP activation
NF-kB
Cellular dysfunction
ATP depletion
Pulmonary dysfunction
Shunt fraction
Loss of hypoxic vasoconstriction

Figure 93-1 Mechanisms of lung parenchymal damage and the role of airway changes following smoke inhalation injury. ATP, adenosine triphosphate; iNOS, inducible nitric oxide; NF-kB, nuclear factor kappa B; PARP, poly(ADP-ribose) polymerase.

It also facilitates airflow within the lung to ensure efficient gas exchange. Following smoke inhalation, the normal function of the airway is compromised. With rare exceptions, such as inhalation of steam, injury to the airway is usually from the chemicals in smoke. The heat capacity of air is low, and the bronchial circulation is very efficient in warming or cooling the airway gases so that most gases are at body temperature as they pass the glottis.[62] Flames must be in almost direct contact with the airway to induce thermal injury.[63]

The chemicals in smoke are dependent on the materials that are being burned; however, for the most part the host response is similar. In most instances, biologic materials such as cotton fabric, wood, or grass, or their products such as cattle feces (commonly used as fuel in developing countries) are the fuel for the fire. These contain caustic materials, such as reactive oxygen (ROS) and nitrogen species (RNS), as well as organic acids and aldehydes.[64] The chemicals interact with the airway to induce an initial response to trigger an inflammatory response.

Although the degree of airway dysfunction may vary depending on the severity of inhalation injury, it can generally be characterized by a few major pathologic alterations that lead to the narrowing/occlusion of the airway lumen, reducing or preventing the normal alveolar gas exchange. The factors leading to the airway lumen narrowing are (1) airway hyperemia; (2) formation of an airway obstructive cast; (3) increased mucus secretion; and (4) bronchospasm (Fig. 93-1).

Airway inflammation plays a major role in the overall response to inhalation injury.

Hyperemia of the airway is such a consistent bronchoscopic finding in smoke inhalation that it is used to diagnose the injury.[65,66] Other variables that are used to establish a diagnosis include injury in an enclosed space, singed nasal hair, and soot in sputum. However, although these findings may be present, the subject may still not develop signs of pulmonary edema characteristic of inhalation injury.

The normal bronchial blood circulation is about 1% of cardiac output. Following smoke inhalation, airway blood flow rapidly increases, resulting in airway wall edema and a leak of protein-rich plasma into the airways. The data presented in Fig. 93-2 highlight the dramatic (10- to 15-fold) increase in tracheal (A) and bronchial (B) blood flow following smoke inhalation that leads to airway wall edema, as confirmed by the macroscopic picture. This illustrates severe edema formation in the tracheal soft tissue compared with the trachea of an uninjured sheep (C).

Many of the studies on the bronchial circulation following smoke inhalation injury have been performed in sheep because these animals have a single bronchial artery[67] and a single lymphatic that drains the lung, allowing for measurement of pulmonary transvascular fluid flux.[68] Abdi et al. reported a 10-fold increase in bronchial blood flow within 20 min of smoke inhalation in sheep.[69] These

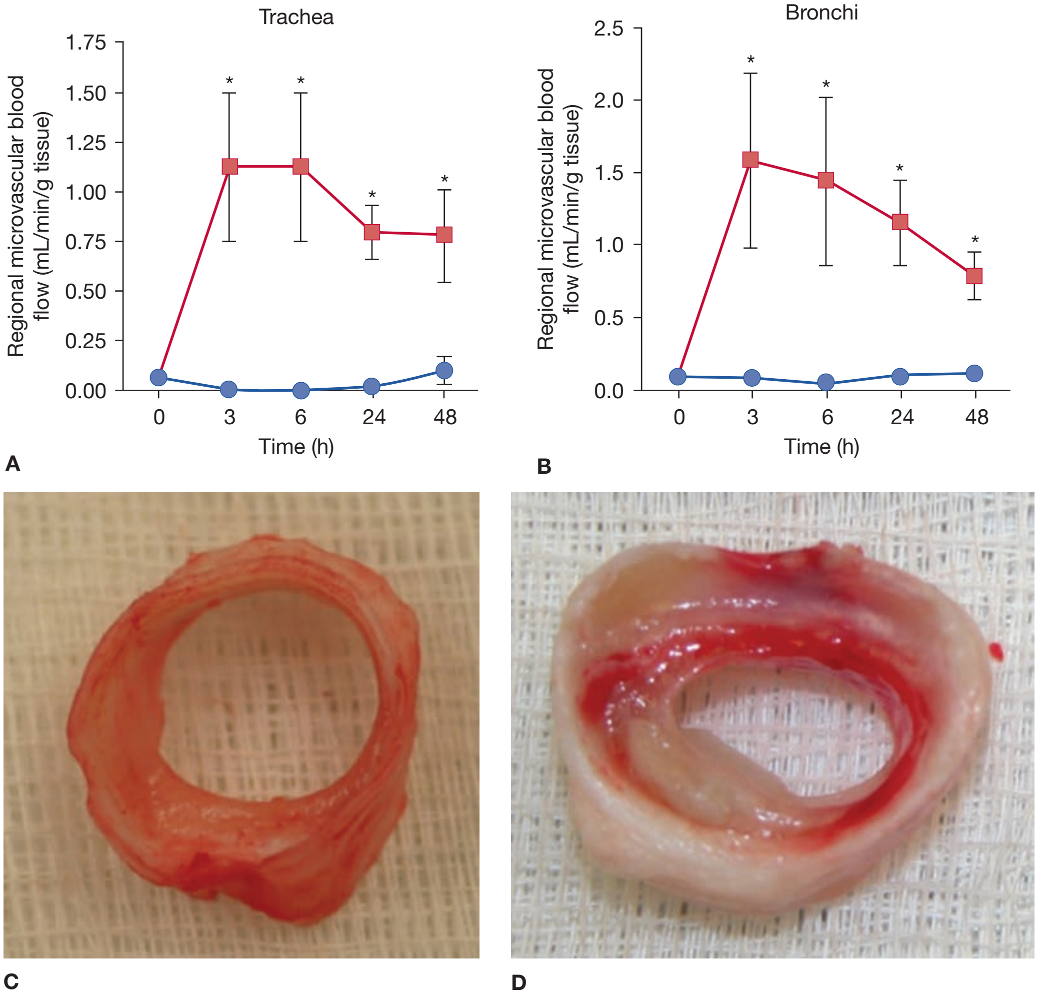


Figure 93-2 Time changes in tracheal (**A**) and bronchial (**B**) blood flow in sheep following cotton smoke inhalation (48 breaths) injury. Blood flow was determined by microsphere injection technique. Data are expressed as ± SEM. $^*p < 0.05$ vs. sham. *Closed circles* represent sheep without injury (sham smoke), and *closed squares* represent sheep with smoke inhalation. **C.** Macroscopic picture of trachea taken at 48 h after sham smoke; and **D.** Macroscopic picture of trachea taken at 48 h after smoke inhalation.

same animals demonstrated a sixfold increase in pulmonary transvascular fluid flux and a fall in $Pa_{O_2}/Fi_{O_2} \leq 300$, but these findings were delayed (24 h).

Similar findings have been reported in patients with smoke inhalation alone, or with the combination of a large cutaneous thermal injury and smoke inhalation.[70] A few investigators have also demonstrated ~10- to 20-fold increases of airway blood flow, depending on the anatomic localization of the airways, using the same model.[71–73] These changes in blood flow are associated with increased bronchial microvascular permeability to protein and small particles[74] and increased pressure.[75] The ablation of bronchial blood flow, by either a ligation of the bronchial artery or the nebulization of adrenergic agonist epinephrine, significantly improved pulmonary gas exchange in the sheep smoke inhalation and burn injury models.[71,73,76,77] Simultaneous with the changes in the function of the bronchial microvasculature, there is a loss or shedding of the bronchial columnar epithelium.[78,79] As noted, these changes result in the formation of a transudate with a protein content similar to an ultrafiltrate of plasma.[80]

The augmented airway circulation not only leads to the airway wall edema, but it also contributes to the formation of airway obstructive casts. In conditions where the basement membrane is impaired due to smoke inhalation, the increased airway blood flow leads to the massive airway transudation. The transudate, containing procoagulants, combines with copious secretions from goblet cells and leukocytes[81] to form a solid airway obstructive cast. Airway obstructive casts not only reduce or prevent normal air passage, they also become a perfect culture media for bacterial growth. In Fig. 93-3, massive airway obstructive casts from human following smoke inhalation injury are shown. The airway obstructive casts, positive for submucosal gland mucus 5B (MUC5B), occupy most of the airway lumen and prevent normal aeration of the alveoli (Fig. 93-4A,B).

Early in the response these secretions are fluid and form a foamy material in the airway that many mistake for severe pulmonary edema in humans.[82] After several hours, this transudate/exudate solidifies or clots in the presence of fibrin, forming firm obstructive materials in the airways. Figure 93-4C shows a presence of fibrin in the airway as a part of the obstructive cast. The mechanism of airway obstructive cast formation is illustrated in Fig. 93-5. These obstructive materials formed in the upper airway may migrate to the lower airways and alveoli.[81] The material is problematic from several stand points. In some rare instances of severe airway injury, the materials can induce total airway obstruction—a life-threatening problem (Fig. 93-3).

The presence of fibrin makes the removal of airway obstructive cast extremely difficult. Occlusion of some of the bronchi or bronchioles in association with high production of NO can lead to

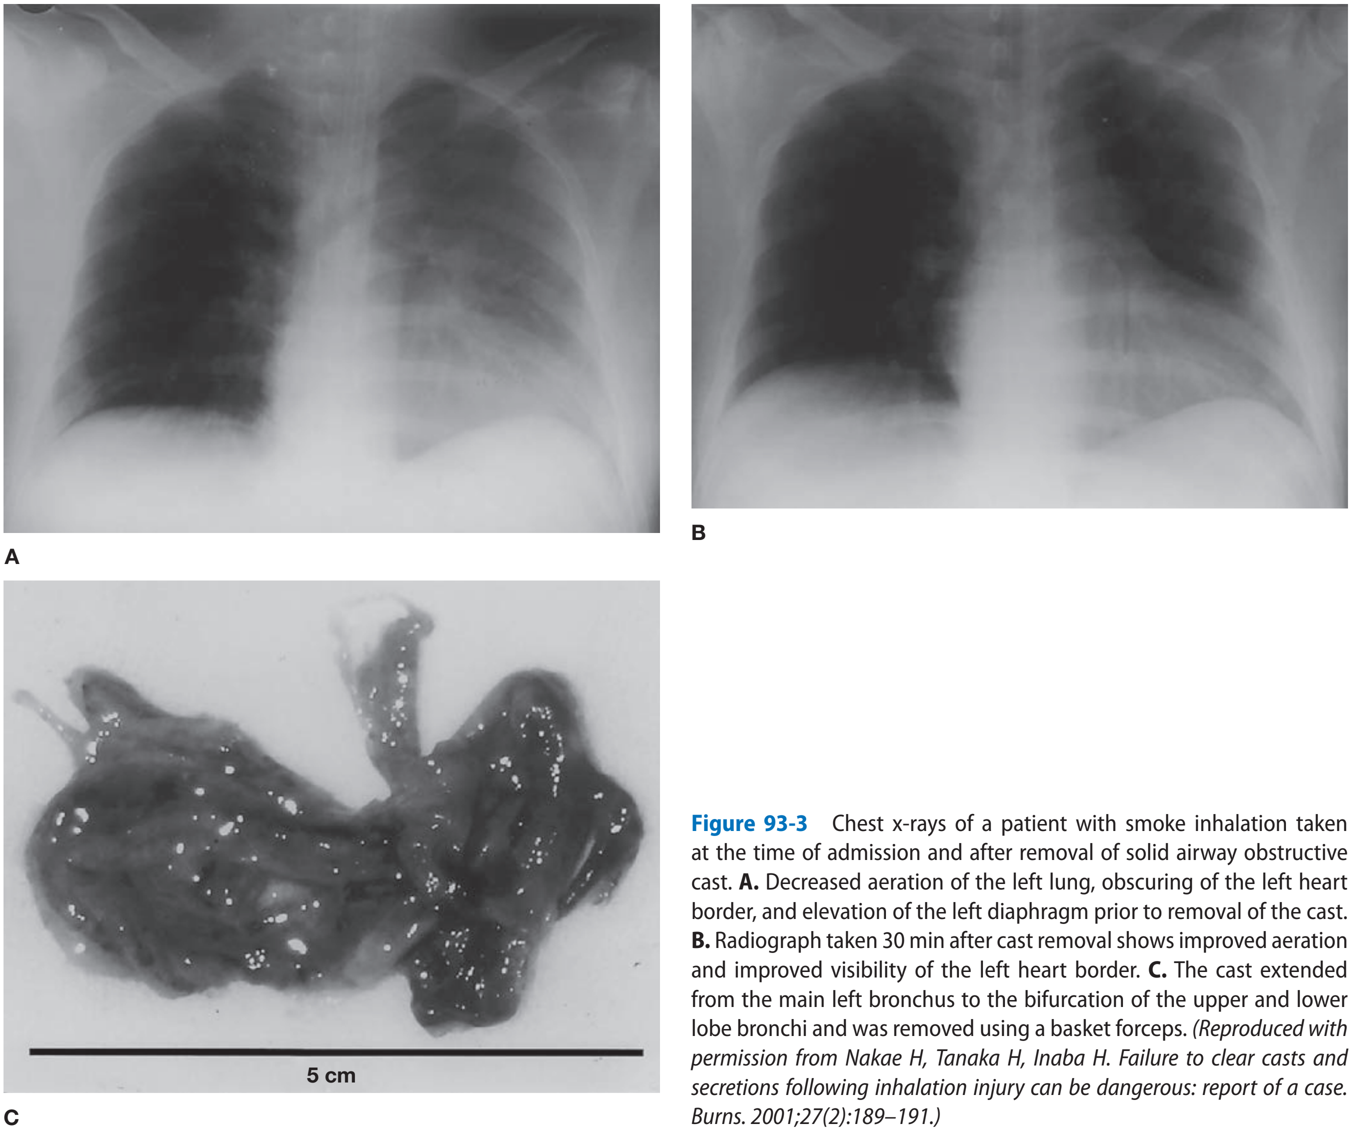

Figure 93-3 Chest x-rays of a patient with smoke inhalation taken at the time of admission and after removal of solid airway obstructive cast. **A.** Decreased aeration of the left lung, obscuring of the left heart border, and elevation of the left diaphragm prior to removal of the cast. **B.** Radiograph taken 30 min after cast removal shows improved aeration and improved visibility of the left heart border. **C.** The cast extended from the main left bronchus to the bifurcation of the upper and lower lobe bronchi and was removed using a basket forceps. *(Reproduced with permission from Nakae H, Tanaka H, Inaba H. Failure to clear casts and secretions following inhalation injury can be dangerous: report of a case. Burns. 2001;27(2):189–191.)*

a loss of hypoxic pulmonary vasoconstriction and increased shunt fraction. In addition, loss of hypoxic pulmonary vasoconstriction with inhalation injury has been reported.[83] Lastly if single bronchi are occluded while the patient is on a volume-cycled ventilator, there could be overstretch and barotrauma to the alveoli of the nonoccluded portion of the lung. In Fig. 93-6, high-resolution computed tomographic *(upper panel)* and magnetic resonance *(lower panel)* images illustrate massive airway obstructive casts and edema surrounding the trachea, main bronchi, and great vessels.

The airway is also richly innervated with vasomotor and sensory nerve endings.[84] It is known that these fibers release neuropeptides in response to caustic materials.[85] Neuropeptide release can cause activation of nitric oxide synthase, stimulate chemokine activity, and change microvascular permeability.[86] The resultant activities lead to formation of reactive oxygen and nitrogen species. Some of the latter are very potent oxidants that can damage DNA. Damage to DNA causes the activation of a repair enzyme poly (ADP-ribose) polymerase (PARP). This enzyme depletes the cell of high-energy phosphates and causes the activation of nuclear factor kappa B (NF-kB). Activation of the nuclear factor causes the upregulation of iNOS and IL-8, creating accelerated production of reactive oxygen and nitrogen species (Fig. 93-1).[44]

NO and 3-nitrotyrosine, an index of reactive nitrogen species, as well as iNOS mRNA and protein have been reported to be elevated in the airway after smoke inhalation.[87] PAR, the product of the constitutive enzyme PARP, was identified in lung tissue following smoke inhalation combined with burn[88] and pneumonia.[89] Inhibition of PARP prevented the formation of PAR, the upregulation of NF-kB, and the formation of 3-nitrotyrosine.[90] Airway inflammation is not

Severe edema surrounding the trachea, main bronchi, and great vessels is present in a craniocaudal gradient. *Double black arrows:* consolidative collapse of the right upper lobe.

seen in a typical asthma model in the presence of a PARP inhibitor or in mice lacking the PARP gene.[90]

■ Lung Parenchyma

As noted above, lung parenchymal changes, as reflected in reduced Pa_{O_2}/Fi_{O_2}, reduced lung compliance, and increased edema formation, are delayed. The delay is dependent on the severity of airway injury.

Lung injury is associated with an increased pulmonary transvascular fluid flux.[87] The degree of transvascular fluid is proportional to the duration of smoke exposure and is independent of the levels of CO in the inhalant gas.[91] The factors responsible for fluid leak are codified in the Starling–Landis equation.[23,92] The variables of this equation relate fluid movement to pressure and permeability variations. With inhalation of smoke there is a reduction in reflection coefficient (permeability to protein), an increase in filtration coefficient (permeability to small particles), and an increase in pulmonary microvascular pressure.[93–95] Figure 93-7 demonstrates that pulmonary transvascular fluid flux in sheep following smoke inhalation is due to changes in both microvascular permeability and pressure. It appears that microvascular changes are responsible for the early event.

Animals that have been exposed to smoke inhalation injury are also noted to have reduced Pa_{O_2}/Fi_{O_2}. The change in this variable

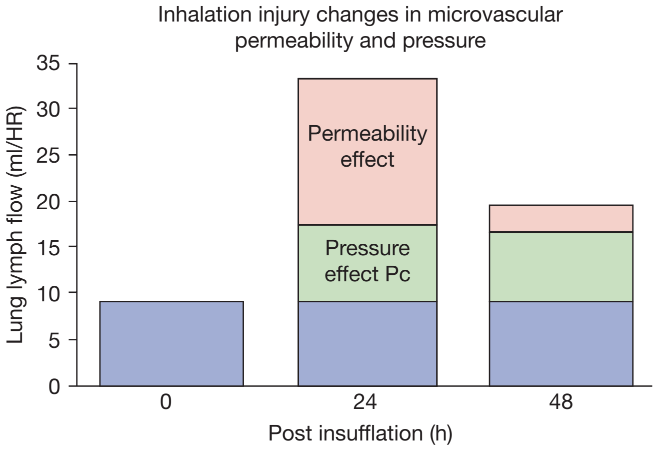

Figure 93-7 Diagram showing portion of edema resulting from either changes in pulmonary microvascular permeability or pressure at 24 and 48 h after inhalation injury. *(Data from Isago T, Fujioka K, Traber LD, et al. Derived pulmonary capillary pressure changes after smoke inhalation in sheep. Crit Care Med. 1991;19(11):1407–1413.)*

shows correlation with the histology injury scores and changes in transvascular fluid flux.[88] In addition, loss of hypoxic pulmonary vasoconstriction in the injured animals helps explain the poor oxygenation seen.[89]

As in the airway, lung parenchymal injury is markedly reduced by administration of iNOS or PARP inhibitors and is associated with the reduction of PAR and 3-nitrotyrosine.[72,87,96]

The venous outflow of the bronchial circulation drains into the pulmonary microcirculation at the precapillary level.[97] The fact that initial damage to the airway appears to drive the pathophysiology of the parenchyma led investigators to hypothesize that the bronchial blood flow might deliver cytotoxic materials or cells into the pulmonary microcirculation. To test this hypothesis, several investigators have tied off the bronchial artery of sheep and then exposed the animals to smoke.[74,71,98] The hypothesis was affirmed in these studies: Lung parenchymal changes were reduced.

Recently, Lange et al. demonstrated that nebulized epinephrine attenuated smoke inhalation–induced increases in both tracheal and bronchial blood flow and improved pulmonary gas exchange.[73] What could be the linkage among the airway, the bronchial venous drainage, and parenchymal injury to the lung? Neutrophils activated in the bronchial circulation flow out into the bronchial venous drainage. Activated polymorphonuclear cells (PMNs), especially neutrophils, are "stiff." The diameter of neutrophils that have been fixed is approximately 7 μm.[99] Since these cells have been dehydrated in alcohol as part of the fixation process, unfixed cells are much larger (on the order of 12 μm). The pulmonary capillary is small, with an average diameter of 6 μm.[99] Normally, the large neutrophil can traverse the pulmonary capillary by changing shape. However, when many neutrophils have been activated in the bronchial areas, their F-actin is activated, and the stiff cells cannot deform. The cells are carried to the pulmonary microvasculature, where they are impaled by the narrow pulmonary capillaries. The activated neutrophils release ROS and proteases that damage the parenchyma.

The following evidence supports this concept of neutrophil cytotoxicity. Oxidative processes are well known following inhalation injury. There is lipid peroxidation and release of proteolytic enzymes following injury.[100–102] Administration of protease inhibitors or scavengers of ROS reduces the response to smoke inhalation[100,103,104] when activated PMNs lose the L-selectin on their surface. This L-selectin shedding is prevented by treatment with an L-selectin antibody.[105] Treatment of the cells with an antibody to L-selectin prevents the changes in transvascular fluid flux and other aspects of parenchymal damage.[106] The final proof of this hypothesis was based on depletion of the animals' neutrophils to determine its effect on the inhalation injury. In studies of sheep depleted of leukocytes, a high percentage of the parenchymal response to smoke inhalation was blocked.[107]

In addition to depletion of antioxidants, it also has been reported that burned patients are depleted of arginine.[108] When arginine levels are low, nitric oxide synthase produces superoxide rather than nitric oxide.[109] Administration of arginine may assist in reducing the oxidation that occurs with inhalation injury. However, the need to administer the arginine as arginine hydrochloride (because of solubility) limits the amount that may be given intravenously without producing acidosis. Efficacy of arginine supplementation was demonstrated in animal models of burn and smoke inhalation injury.[110]

Smoke inhalation injury, especially when it is combined with cutaneous burns, causes both local airway and systemic coagulopathy.[111–114] The hypercoagulable state in burn patients during the initial 24 h is associated with high levels of activated factor VII (FVIIa), thrombin-antithrombin complex (TAT), and PAI-1, and low levels of antithrombin.[115] In concert, the results of these studies may suggest that a high rate of fibrin or thrombin formation and its diffuse deposition in the microvasculature during the first days following injury, along with a relatively ineffective fibrinolysis due to excess PAI-1, may play an important pathophysiologic role in the development of organ dysfunction.

■ Treatment

Treatment of smoke inhalation is complex. There is no defined and uniformly accepted standard, and the therapeutic approach varies among burn centers. An example of an evidence-based protocol for patients (0–18 years) with smoke inhalation injury at Shriners Hospitals for Children at Galveston[116] is summarized in Table 93-5.

The airway is a major concern immediately after the inhalation injury. Airway management is very difficult in patients with combined burn and inhalation injuries. Intubation of patients with burns of the soft tissues of the face, oropharynx, and neck is challenging. Burn injury to these areas results in almost immediate and severe edema and swelling.[117] Intubation in such an individual requires great skill. Securing the tube also is difficult. Accidental removal of the endotracheal tube can easily happen and may be

TABLE 93-5 Example of an Evidence-based Protocol for Patients (0–18 years) with Smoke Inhalation Injury

- Titrate humidified high-flow oxygen to maintain SaO_2 >90%
- Cough, deep breath exercises every 2 h
- Turn patient side to side every 2 h
- Chest physiotherapy every 2 h
- Nebulize 20% N-acetylcysteine (3 mL) every 4 h for 7 days; co-nebulize with a bronchodilator (albuterol) if wheezing
- Alternate aerosolizing 5000–10,000 units of heparin (in 3 mL normal saline) every 4 h for 7 days
- Nasotracheal suctioning as needed
- Early ambulation
- Sputum cultures for intubated patients every Monday, Wednesday, and Friday
- Pulmonary function studies at discharge and at outpatient visits
- Patient and family education about the disease process

lethal. Often burns and/or the chemicals in smoke can damage the larynx, and placement of the tube may cause damage and delay healing. Tracheostomy is sometimes performed but may be difficult if the tube has to be placed through burned skin on the neck. For information on this, the reader is referred to chapters in Herndon's *Total Burn Care*.[118,119]

To prevent airway obstruction, vigorous airway toilet should be performed. The airway cast material contains fibrin. Experimentally, use of heparin has been reported to be effective in reducing airway obstruction.[120] Many burn units nebulize heparin into the airways of patients with inhalation injury.[121] Of note, heparin requires the presence of antithrombin to be effective, and this factor has been reported to be deficient following burn injury.[113,122] Consequently, antithrombin has been reported as effective in these situations in animal studies.[113,114,123–126] Intravenous administration of antithrombin has also been shown to reduce mortality and morbidity in burn patients.[127] Antithrombin may also act as an anti-inflammatory agent.[128] Because concomitant use of heparin prevents antithrombin's anti-inflammatory effects, administration of these compounds by different routes was suggested in large animal, translational studies (i.e., heparin administration via nebulization and systemic administration of antithrombin, to achieve maximum local [airway] anticoagulant and systemic anti-inflammatory effects).[113,129] Tasaki et al. also reported beneficial effects of nebulized heparin combined with intravenous infusion of anti-inflammatory agents.[130]

Once obstructive materials have formed in the airway, anticoagulant therapy (heparin and antithrombin) is ineffective in their removal. Animal studies have demonstrated that tissue plasminogen activator can be effective.[112] Aerosolized tissue plasminogen activator has also been reported to be useful in removing bronchial obstructive material in patients who have had Fontan procedures for complex congenital heart diseases.[131,132]

To alleviate airway smooth muscle spasm, nebulized albuterol has been used successfully both in an animal model of smoke inhalation and in burn patients with concomitant smoke inhalation.[133,134] Other bronchodilators, such as nebulized tiotropium bromide and epinephrine, have been shown to be beneficial in an animal model of inhalation injury.[73,135]

Because of almost immediate airway hyperemia following smoke inhalation, use of nebulized agents that modulate augmented airway blood flow may be of particular importance. Lange et al. recently reported that nebulized epinephrine, a nonspecific adrenergic agonist, reduced both tracheal and bronchial blood flow and improved arterial oxygenation in a sheep model of cotton smoke injury.[69] Lopez et al. confirmed the latter result that nebulized epinephrine reduced airway mucosal and pulmonary parenchymal edema in sheep with combined burn and smoke inhalation.[136]

Nebulized epinephrine may be of particular interest in management of inhalation injury since it has both alpha (vasoconstriction) and beta (bronchodilation) effects. Recently, Fukuda et al. reported superior effects of nebulized epinephrine versus nebulized albuterol, as well as nebulized phenylephrine (specific α1-adrenergic receptor agonist) in ameliorating severity of acute lung injury in an ovine model of combined burn and smoke inhalation,[137] confirming that both alpha and beta agonist effects are required for more efficient management of airway dysfunctions. The safety of the nebulized epinephrine was also tested in a pilot clinical study involving pediatric burn patients with concomitant smoke inhalation injury.[138] However, further larger clinical studies are needed to assess the safety and efficacy of such therapy.

The importance of reducing airway hyperemia has been repeatedly shown in animal models by ablating the bronchial artery.[71,74,76,77,98] Local administration of various compounds to the bronchial artery that attenuate inflammation prevents many pathologic changes following smoke and burn injury in sheep.[139–141] Although such therapies (ligation and cannulation of bronchial artery for drug infusion) are not feasible in clinical practice, these findings strongly suggest the critical role of airway dysfunction (hyperemia, inflammation) in the pathophysiology of lung injury after smoke inhalation. The findings also suggest the crucial importance of efficient airway management in alleviating severe lung injury following smoke inhalation.

Many other drugs have also proved effective in reducing the injury to the lung parenchyma of animal models of inhalation injury, including cyclooxygenase inhibitors,[142] iNOS inhibitors,[72] PARP inhibitors,[23] and free radical scavengers,[103] as well as the anticoagulant factors[113,129] mentioned above. However, only the last noted are in clinical use and/or have been studied in clinical trials.[129,143]

Recent preclinical studies propose the use of cellular therapy. Ihara et al. demonstrated efficacy of intravenously administered adipose-derived mesenchymal stem cells (MSCs) in sheep with severe smoke inhalation injury.[144] Asmussen et al. reported beneficial effects of human bone marrow–derived MSCs in an ovine acute lung injury model induced by smoke inhalation and pneumonia.[145] Further studies are needed to investigate possible long-term safety issues related to possible malignancy.

Optimal dose-determining studies in patients with or without concomitant skin burns should be performed. A recent report by Baljinnyam demonstrated that skin burns diminish the beneficial effects of MSCs on smoke-induced lung injury by promoting migration of MSCs from the pulmonary tissue to the injured skin area, possibly via expression of Sdf-1 protein.[146]

Mechanical ventilation is indicated in cases of respiratory failure. However, mechanical ventilator management is challenging. Because of severe airway pathology, including massive airway obstructing casts, airway mucosal edema, and the presence of chest wall thermal injuries, in many instances, conventional methods of ventilation can no longer sustain pulmonary function. Sousse et al. retrospectively compared the effects of high (15 mL/kg) and low (9 mL/kg) tidal volume ventilation in pediatric burn patients and concluded that high tidal volume ventilation significantly decreased ventilator days, PEEP requirements, and the incidence of atelectasis, despite an increased incidence of pneumothorax.[147] The results of this study suggest that burn patients with smoke inhalation may require mechanical ventilation with higher tidal volumes than usually recommended. However, a prospective, multicenter clinical trial is needed to carefully weigh benefits versus harm.

To overcome the conventional ventilation challenges in burn patients with smoke inhalation, alternative methods, including percussive ventilation, have been proposed.[148] High-frequency percussive ventilation (HFPV) has been shown to improve oxygenation,[149] decrease the incidence in pneumonia, and improve survival.[148] In addition, it has been suggested that HFPV is superior to other methods of percussive ventilation, for example, high-frequency oscillatory ventilation and high-frequency jet ventilation.[150]

Hale et al. reported that independent of ventilatory method, simple prone positioning improves oxygenation in adult burn patients with severe acute respiratory distress syndrome, inducing a prompt increase in the Pa_{O_2}/Fi_{O_2} ratio. The authors concluded that prone positioning can be safely used in a burn intensive care unit to achieve an increase in Pa_{O_2}/Fi_{O_2} ratio.[151]

Extracorporeal membrane oxygenation (ECMO) has been used in burn patients with some success.[152] Techniques have now been developed in animal models of inhalation injury that involve a unique form of CO_2 removal called arteriovenous CO_2 removal or AVCOR. Off-the-shelf CO_2 removal devices used in extracorporeal bypass and cardiopulmonary bypass have been modified to enable the devices to be driven by the subject's own arterial pressure.[153] The devices were tested in animal models and shown to be very successful in reducing pathophysiologic measures, morbidity, mortality, and days of ventilatory support in models of inhalation injury.[154–156]

Finally, some pretreatment for smoke inhalation should be considered. People who are chronically exposed to smoke, such as farmers who burn crops, individuals with fires in their huts, and fire fighters may benefit from pretreatment. For example, there are reports that individuals who are chronically exposed to smoke are depleted of antioxidants.[157] Consequently, supplementation of antioxidants should be considered.[157]

CONCLUSION

The diagnosis and treatment of smoke inhalation injury are complex. Standardized criteria for the diagnosis of smoke inhalation injury and recommendations for use of specific pharmacologic agents are lacking. Multicenter, prospective, randomized, large-scale clinical trials are needed to test the efficacy and safety of promising pharmacologic agents identified in basic and translational studies (e.g., nebulized fibrinolytics, anticoagulants, beta or mixed beta- and alpha-adrenergic agonists, antioxidants).

ACKNOWLEDGMENT

Dedicated to the memory of Dr. Daniel L. Traber, who was my mentor and the coauthor of this chapter in the previous edition.

CHAPTER 94

Noninfectious Pulmonary Complications of Hematopoietic Stem Cell and Solid Organ Transplantation

Robert M. Kotloff

HEMATOPOIETIC STEM CELL TRANSPLANTATION

Hematopoietic stem-cell transplantation (HSCT) is a potentially curative treatment option for hematologic and lymphoid cancers, selected solid tumors, and nonneoplastic diseases, including autoimmune disorders, amyloidosis, and aplastic anemia.[1] Since the first HSCT was performed in 1956, there has been a steady increase in the number performed worldwide, with more than 35,000 autologous and 30,000 allogeneic HSCTs now performed annually.[2] In the United States in 2018, a total of 9028 allogeneic and 14,006 autologous HSCTs were performed.[3] As peritransplant management strategies have improved, HSCTs are being performed increasingly often for a wider range of conditions, and in patients who are older and with more comorbidities.

During HSCT, patients undergo high-dose conditioning chemotherapy and/or radiation therapy with a view to eradicate their immune system along with any residual malignant cells. Stem cells are collected beforehand and are administered after conditioning is complete to reconstitute the immune system. HSCT may be autologous (where the donor stem cells are the patient's own) or allogeneic (where the donor stem cells are from an appropriately matched donor). The main indications for autologous transplant include multiple myeloma and lymphomas. The main indications for allogeneic transplants include acute and chronic leukemia, lymphoma, and myelodysplastic syndrome. Stem cells are typically harvested from peripheral blood after mobilization with agents such as G-CSF, cyclophosphamide, and plerixafor, but they can also be harvested directly from bone marrow or from cord blood.[3]

Autologous HSCT is always myeloablative: the conditioning regimen needs to eradicate any malignant cells that remain after induction chemotherapy, so no residual marrow remains. Allogeneic HSCT has intrinsic graft-versus-tumor effect, where the donor bone marrow attacks residual tumor cells. This allows for the option of nonmyeloablative and reduced-intensity conditioning regimens. These regimens are lower intensity so may leave residual tumor cells behind, but they are also easier to tolerate for older patients and those with more comorbidities.

Following HSCT, the immune system recovers along predictable patterns depending on the underlying disorder, type of transplant, stem cell source, and posttransplant complications.[4] Recovery occurs faster in autologous transplant recipients, in those who receive peripheral blood stem cell grafts, and in those allogeneic transplant recipients who receive nonmyeloablative conditioning. The posttransplant period is classically divided into three phases: peri-engraftment, early posttransplant, and late posttransplant.[5] The peri-engraftment phase (0 to 30 days) is characterized by neutropenia and breaks in the mucocutaneous barriers with a high burden of sepsis, pneumonia, aspiration, and critical illness. The early post-engraftment phase (30–100 days) is characterized by impaired cell-mediated immunity. The impact of this cell-mediated defect is greater in allogeneic transplant recipients who are prone to the development of GVHD, often resulting in the initiation of immunosuppressant medications further increasing their risk of opportunistic infection. The late posttransplant phase (>100 days) is characterized by defects in cell-mediated and humoral immunity, as well as dysfunction of the reticuloendothelial system in allogeneic transplant recipients.

While the development of noninfectious pulmonary complications is traditionally divided into this characteristic triphasic temporal pattern, it represents a dynamic, individualized spectrum of risk (Fig. 94-1).[6,7] Peri-engraftment respiratory distress syndrome (PERDS) occurs by definition in the first 30 days of transplant, typically in the few days prior to neutrophil engraftment (defined as the first of 3 consecutive days where absolute neutrophil count exceeds 500 cells per mm).[3,8] During this early posttransplant period, patients are also more susceptible to pulmonary edema, acute respiratory distress syndrome (ARDS), and diffuse alveolar hemorrhage.[9] Idiopathic pneumonia syndrome (IPS), a form of idiopathic posttransplant ARDS, can occur at any time after transplant.[10] Bronchiolitis obliterans syndrome (BOS), a form of lung GVHD, occurs in the late posttransplant phase.

Although HSCT survivorship has steadily improved in the last two decades, mortality after transplant remains substantial and is dependent on a number of factors.[3] The underlying disease affects both the type of transplant received and the likelihood of survival. For example, a patient with aplastic anemia undergoing allogeneic HCT would have a 3-year survival of 80% compared with 51% for a patient undergoing the same type of transplant for myelodysplastic syndrome. The disease status at the time of transplant also is important. A patient with early-stage AML has a 3-year survival of 58%, but this drops to 29% in those with advanced-stage AML at the time of transplant. Similarly, a chemosensitive lymphoma typically has survival 10% to 15% higher at 3 years than a chemoresistant lymphoma. Autologous transplants are done selectively in certain diseases, most commonly myeloma and amyloidosis. Patients who have disease relapse after autologous HSCT are eligible for repeat HSCT. However, survival after a second transplant is substantially lower (3-year survival, 58%) compared with patients undergoing first-time transplant (3-year survival, 76%).

Early posttransplant mortality (within 100 days) is due to disease relapse in approximately one-third of those who die. The other common causes are infection, organ failures, and GVHD (in allogeneic transplant recipients). Late posttransplant mortality (after 100 days) is due to disease relapse in the vast majority (~80%) of autologous transplant recipients. In allogeneic transplant recipients, disease relapse is responsible for ~60% of deaths, with 15% due to GVHD, 10% due to graft rejection, and 15% due to infection.[3] The likelihood of infection after allogeneic transplant is typically higher than after autologous transplant due to both a longer posttransplant period of neutropenia and the need for long-term immunosuppressive medications for GVHD treatment.

■ Frequency of Pulmonary Complications

Pulmonary complications are common after HSCT (Table 94-1). In a prospective series of 175 patients undergoing HSCT published

in 2014, 73 pulmonary complications were observed in 51 (30%) patients.[11] Of these events, 21 (29%) were noninfectious complications. Allogeneic transplant recipients were more likely to have pulmonary complications than autologous transplant recipients (58% vs. 24%). Interestingly, in a 1986 series of 130 allogeneic HSCT recipients, 69 of 130 patients (53%) developed pulmonary complications. The remarkably similar rates of pulmonary complications after allogeneic HSCT over an almost 30-year period highlight not only the severe impact of pulmonary complications on post-HSCT outcomes but also the need for further research in this area.

TABLE 94-1 Noninfectious Pulmonary Complications in the HSCT Recipient

Early (usually <100 days)
Upper airway complications
Pulmonary edema
Diffuse alveolar hemorrhage
Peri-engraftment respiratory distress syndrome
Idiopathic pulmonary syndrome

Late (usually >100 days)
Bronchiolitis obliterans syndrome
Organizing pneumonia
Delayed pulmonary toxicity syndrome
Eosinophilic pneumonia
Interstitial lung disease
Pulmonary alveolar proteinosis
Pleuroparenchymal fibroelastosis
Any time
Isolated abnormality in pulmonary function
Pulmonary veno-occlusive disease

The lower rates of pulmonary complications after autologous transplantation compared with allogeneic HSCT are supported by other series. For example, in a series of 1243 autologous HSCT recipients, 383 patients (27.6%) developed pulmonary complications, with noninfectious diagnoses in 10.2%.[12] In this series, the hazard ratio for death in those who had pulmonary complications was more than 30 times higher than those who did not.

Pulmonary complications appear to be similarly common in the pediatric HSCT population, although the epidemiology is less well characterized. For example, in a series of 363 pediatric HSCT recipients, 90 (25%) developed pulmonary complications.[13] Late-onset noninfectious pulmonary complications described include BOS and IPS.[14]

Impact of Pulmonary Complications on Patient Outcomes

As overall transplant survivorship has improved, there is an increased focus on identifying ways to reduce nonrelapse mortality.[3,15] Pulmonary complications remain a major threat to the survival of the transplant recipient. In a prospective series, pulmonary complications were the most common cause of mortality within the first year of transplant and represented 41% of nonrelapse mortality.[11]

Early pulmonary complications often necessitate urgent hospital or ICU admission, and a substantial number of patients need invasive and noninvasive ventilatory support. The etiology of these early complications is varied (Table 94-2) and sometimes cannot be identified. In a cohort of 2635 patients, 133 (5.0%) developed ARDS.[9] ARDS developed typically within the first 3 months of transplant and was associated with an in-hospital mortality of 57%. Although prognosis of such severe respiratory failure after HSCT is grim, overall mortality appears to have decreased over time.[16–18] Disease-specific outcomes are addressed in the relevant sections of this chapter.

Late-onset pulmonary complications are often noninfectious and include BOS, interstitial lung diseases, and pulmonary vascular diseases. These conditions often initially present subacutely in the outpatient setting. The impact of late-onset noninfectious pulmonary complications is substantial, including reduced exercise

TABLE 94-2 Risk Factors for Pulmonary Complications in HSCT Recipients

Preexisting lung disease

Time interval between underlying diagnosis and transplant
Time elapsed since transplant
Graft-versus-host disease

capacity, oxygen dependence, and mortality in excess of 50%.[19–25] In patients who survive more than 2 years after transplant, pulmonary complications accounted for 5% of the subsequent deaths, and patients with pulmonary complications had a 15-fold increased risk of death.[26]

Approach to the Diagnosis of Noninfectious Pulmonary Complications

The diagnostic approach to the HSCT recipient with suspected noninfectious pulmonary complications should follow a systematic approach.[7] Recipients with respiratory symptoms and signs usually are evaluated with a chest radiograph followed by high-resolution computed tomography (HRCT). If the radiographic evaluation fails to reveal pulmonary infiltrates, especially in allogeneic recipients, PFT should be performed to assess for BOS. For patients with pulmonary infiltrates, noninvasive tests should be performed for infections and other causes. Noninvasive approaches include multiplex nasopharyngeal swab PCR assays,[27] sputum for microbiology studies, blood culture, galactomannan and β-D-glucan assays,[28,29] cytomegalovirus (CMV) viral load testing, and urine antigen testing for *Legionella pneumophila* and pneumococcal pneumonia.[30] If noninvasive testing is nondiagnostic, invasive techniques should be considered, balancing the risk-benefit ratio. The invasive approach usually relies on fiberoptic bronchoscopy with bronchoalveolar lavage (BAL) and occasionally transbronchial lung biopsy. Other invasive procedures such as image-guided transthoracic needle aspiration and video-assisted thoracoscopic biopsy rarely may be needed.[31]

Pulmonary Function Testing

Pulmonary function testing is part of the routine pretransplant evaluation performed when determining eligibility for both autologous and allogeneic HSCT. Since both the chemotherapy agents and radiation therapy used for pretransplant conditioning have pulmonary toxicities,[32] having baseline pulmonary function testing can be valuable when monitoring for drug- and/or radiation-induced lung injury. Baseline pulmonary function testing can also be helpful when evaluating for specific post-HSCT lung injury syndromes such as BOS.

In addition to serving as a baseline, there appears to be prognostic value in assessing pulmonary function testing.[33] Multiple series have demonstrated that poorer pretransplant PFTs are associated with an increased risk of posttransplant pulmonary complications and mortality.[34–36] In one such series, authors developed a pretransplant Lung Function Score incorporating forced expiratory time in 1 s (FEV_1) and diffusing capacity (DL_{CO}).[33] Using this score, they found impairments in pretransplant pulmonary function were associated with a greater probability of post-HSCT pulmonary complications, and that risk appeared to increase with increasing impairment of pretransplant pulmonary function. As a result, the widely used hematopoietic cell transplant (HCT)-specific version of the Charlson Comorbidity Index (HCT-CI) incorporates pretransplant FEV_1 and DL_{CO} in its composite risk score.[37] Increased HCT-CI scores are associated with reduced overall posttransplant survival, especially related to nonrelapse mortality.[38–40] Pulmonary function testing is typically performed routinely for all patients since some patients can have pulmonary function abnormalities in the absence of respiratory symptoms.[41]

Pretransplant pulmonary function studies may also have prognostic implications for developing *specific* posttransplant noninfectious pulmonary complications. For example, in a cohort of patients undergoing HSCT, pretransplant FEV_1 and DL_{CO} were associated with developing posttransplant IPS.[42] Those with severe pretransplant impairment in pulmonary function had increased risk of mortality from IPS.

Pulmonary function testing can also be used as a method for detection of posttransplant pulmonary complications. The development of pulmonary function test abnormalities after HSCT is associated with increased post-HSCT mortality.[43–46] For example, in a series of allogeneic HSCT recipients, most patients had normal pulmonary function after HSCT.[46] However, those with impaired post-HSCT pulmonary function parameters (FEV_1 and DL_{CO}) at 80 days post-HSCT had increased risk of nonrelapse mortality. A low FEV_1 was specifically predictive for developing chronic GVHD. HSCT recipients with IPS or organizing pneumonia (OP) present with restrictive pulmonary function impairment, and those with BOS demonstrate airflow obstruction.[47]

Risk factors for the development of pulmonary function abnormalities following HSCT include smoking history, pretransplant pulmonary infection, viral infection in the early posttransplant period, older age, underlying disease, pretransplant chemotherapy and conditioning regimen, GVHD, and HLA mismatch.[48–51] Respiratory muscle weakness, an alternative cause of restrictive pulmonary function abnormalities, was reported in 52% of allogeneic HSCT recipients in a retrospective study.[52] Risk factors for respiratory muscle weakness include chemotherapy, total body irradiation, high dose corticosteroids, immobility, and GVHD.[52]

Early Noninfectious Pulmonary Complications

HSCT recipients are prone to numerous pulmonary complications in the early (<100 days post-HSCT) transplant period (Table 94-3). These are broadly divided into infectious and noninfectious, and all patients with suspected noninfectious syndromes should have some form of evaluation for infection. Those presenting with acute hypoxemic respiratory failure present along a spectrum of severity, and many meet criteria for ARDS. While the underlying etiology is often not known at the time of initial presentation, the principles of ARDS management and prevention apply in this population. Specifically, this includes lung-protective mechanical ventilation with low tidal volumes as well as use of neuromuscular blockade and prone positioning where appropriate.[53–57] In addition, there should be a focus on preventing further iatrogenic injury through judicious fluid and blood product administration, aspiration precautions, and early focus on mobilization and ventilator liberation.[55,58] Several specific post-HSCT noninfectious syndromes have been described, and these are outlined below. Importantly, the post-HSCT lung injury syndromes of ARDS[9]—PERDS,[59] IPS,[10] and DAH[60]—are all overlapping in their clinical presentations, and likely also in their pathophysiologic underpinnings.

TABLE 94-3 Definitions of the Early Post-HSCT Lung Injury Syndromes

Post-HSCT Complication	Definition
Peri-engraftment respiratory distress syndrome	1. Development of new bilateral pulmonary infiltrates 2. Hypoxemia 3. Clinical syndrome not fully explained by an infectious process, fluid overload, or heart failure 4. Occurring within 5 days of either side of the neutrophil engraftment date; this is defined as the first of three consecutive days in which the absolute neutrophil count surpasses 500 cells/mm^3 following transplantation
Diffuse alveolar hemorrhage	1. Respiratory failure requiring supplemental oxygen or noninvasive or invasive ventilation 2. Evidence of bilateral pulmonary infiltrates on chest x-ray or lung CT 3. The presence of (a) progressively hemorrhagic return with serial aliquots during bronchoalveolar lavage, and (b) ≥20% hemosiderin-laden macrophages on cytopathology Definite DAH: criteria (1), (2), and both criteria in (3) Probable DAH: criteria (1), (2), and one criterion in (3)
Idiopathic pneumonia syndrome	1. Multilobar opacities on chest radiograph or computed tomography 2. Signs and symptoms of pneumonia 3. Evidence of abnormal pulmonary physiology manifested by an increased alveolar–arterial oxygen gradient or the need for supplemental oxygen 4. Absence of lower respiratory tract infection, as determined by a negative bronchoalveolar lavage 5. Clinical syndrome not fully explained by fluid overload or heart failure
Acute respiratory distress syndrome	1. Bilateral pulmonary opacities on chest imaging. 2. PF ratio <300 mm Hg with a minimum of 5 cm H_2O positive end-expiratory pressure (can be with invasive or noninvasive ventilation) 3. Clinical syndrome cannot be fully explained by cardiac failure or fluid overload 4. Occurring over 1 week or within 1 week of an inciting event

Pulmonary Edema

Acute pulmonary edema is relatively common during the neutropenic phase. In a review of more than 1200 autologous HSCT recipients, pulmonary edema was felt to be present in 4.7% of patients.[12] Patients may have preexisting cardiac dysfunction due to chemotherapy (especially cyclophosphamide and anthracyclines) or radiation therapy. Since echocardiography is routine during pretransplant evaluation, this is usually known ahead of time. Direct injury from therapies, such as total body irradiation and induction chemotherapy, may lead to endothelial injury, making pulmonary edema more likely. Patients often receive intravenous fluids due to reduced oral intake, mucositis, or increased insensible losses from fevers or diarrhea. Patients also receive numerous intravenous infusions such as antibiotics and sometimes total parenteral nutrition. Lastly, patients receive red blood cell and platelet transfusions for chemotherapy-induced cytopenias. Blood products can predispose patients to both transfusion-associated circulatory overload (TACO) and transfusion-associated acute lung injury (TRALI).[61–63] Taken together, all these factors can combine to leave patients at increased risk of pulmonary edema in the immediate posttransplant period. Importantly, while some of these factors are unavoidable, pulmonary edema is largely an iatrogenic complication that can usually be prevented.

Upper Airway Complications

Significant injury to the mucosal barrier occurs in about 75% of HSCT recipients, and oral mucositis represents a major source of early post-HSCT morbidity.[64] Mucositis typically peaks between days 6 and 12 after HSCT[65] and is associated with patient discomfort, impaired nutrition, increased hospitalization, and higher post-HSCT mortality.[66,67] Total body irradiation, allogeneic transplant, delayed neutrophil engraftment, higher chemotherapy doses, and increased weight are all risk factors for mucositis.[68,69] Upper airway inflammation due to mucositis may lead to laryngeal edema, dysphagia, and aspiration pneumonia. Life-threatening upper airway complications can occur and are more common in children.[70,71] Use of narcotics to manage mucositis-related pain can further increase the risk of aspiration, and requirement for parenteral nutrition can increase the risk for bloodstream infections.[69,68] Upper airway injury in HSCT recipients is usually managed with supportive care, including local symptomatic therapy. Endotracheal intubation is typically only needed when mucosal sloughing represents an acute airway threat. Intubation in this setting can be highly challenging and should be done by experienced airway specialists with appropriate advanced airway backup.

Peri-engraftment Respiratory Distress Syndrome

The engraftment syndrome is an incompletely understood condition that occurs during the early posttransplantation period following autologous HCT.[59,72,73] The clinical features of engraftment syndrome include noninfectious fever, skin rash, hypoxemia, pulmonary infiltrates, weight gain, and hypoalbuminemia, all occurring around the time of neutrophil recovery. When engraftment syndrome has pulmonary manifestations, it is referred to as the peri-engraftment respiratory distress syndrome (PERDS). Precise estimates of incidence of engraftment syndrome are difficult to determine due to the nonspecific nature of the syndrome and heterogeneity in diagnostic criteria, with reports indicating incidence of anywhere between 7% to 53% of HSCT recipients.[59,72,74,75] Mild cases may be subclinical and thus not detected. Although most of the studies reporting engraftment syndrome are in autologous HSCT recipients, it has been rarely reported after allogeneic transplantation as well.[76,77]

Frequency, Risk Factors, and Pathogenesis The incidence of PERDS is estimated to be between 4% and 5% after autologous HSCT, with the largest series showing an incidence of 4.8% in a cohort of more than 3500 autologous HSCT recipients.[8,12,78] PERDS occurs at time of neutrophil engraftment, typically between 9 and 16 days after autologous HSCT (median, 13 days).

Several risk factors have been identified for the development of PERDS. These include POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, skin changes) syndrome, female sex, a more rapid time to engraftment, use of G-CSF, and increased platelet transfusions in the immediate posttransplant period.[72,77–81]

The pathogenesis of PERDS is not well defined but is believed to represent an interaction between conditioning-related endothelial damage and the cytokine release associated with neutrophil and lymphocyte recovery.[8] Tissue infiltration by neutrophils has been shown to occur earlier than their appearance in the peripheral blood, and radiographic changes precede diagnosis in the majority of cases.[78,82] The association between PERDS and POEMS also supports the proinflammatory hypothesis, as patients with POEMS are known to have elevations of a variety of circulating cytokines.[79] It is possible that this proinflammatory state makes patients more vulnerable to the consequences of cytokine release during neutrophil engraftment, resulting in a greater risk of PERDS.

Clinical Findings and Diagnostic Evaluation Patients with PERDS present with nonspecific pulmonary symptoms (dyspnea, cough), typically accompanied by hypoxemia. While other features of engraftment syndrome may be present, PERDS may be the initial or only feature in some patients.[8,72,83] The majority of patients with PERDS require hospitalization. Over 50% require ICU admission and 20% require mechanical ventilation.[78]

The diagnostic criteria for PERDS are not standardized, but the diagnosis should be considered in autologous transplant recipients who develop new bilateral pulmonary opacities on chest imaging and hypoxemia within 5 days on either side of the neutrophil engraftment date (defined as the first of 3 consecutive days in which the absolute neutrophil count surpasses 500 cells/mm^3 following transplantation). The radiographic changes may precede engraftment by several days.[78] Although attempts should be made to rule out infection, most patients do not undergo BAL unless they are already on mechanical ventilation.[12] This is largely due to the self-limited nature of the disease and the invasive nature of the procedure. Biopsy is prohibitively high risk due to thrombocytopenia and not considered necessary for the diagnosis. Lung histology from patients with PERDS shows diffuse alveolar damage.[8]

Treatment Unlike other post-HSCT lung injury syndromes, PERDS appears to be relatively responsive to steroid therapy, but this is based on low-quality evidence derived from observational case series, with substantial risk of bias. For example, in one study, 40 of 41 patients with engraftment syndrome who received steroids demonstrated symptomatic or clinical improvement.[8,72] Steroid courses are typically 1 to 2 mg/kg methylprednisolone twice daily for 3 days, followed by a rapid taper.

Outcomes and Prognosis While there is considerable morbidity associated with PERDS, the prognosis is substantially better than for other post-HSCT lung injury syndromes (e.g., DAH, IPS, ARDS). PERDS is associated with increased rates of ICU admission compared with autologous HSCT recipients who do not develop PERDS (47% vs. 10% in one series).[78] Patients diagnosed with PERDS are more likely to require ventilatory support and have longer ICU and hospital lengths of stay. Case-fatality rates have decreased from greater than 20% nearly two decades ago to less than 5% in the current era.[8,78]

Diffuse Alveolar Hemorrhage

Although alveolar hemorrhage can occur in the setting of pulmonary infection, the syndrome of DAH typically refers to alveolar hemorrhage where no infectious etiology is identified.[84]

Diagnosis There are no standardized or widely accepted diagnostic criteria for DAH after HSCT. In an attempt to standardize the definition, we have recently proposed the following criteria, which are extrapolated from clinical practice and other alveolar hemorrhage syndromes.[85] Definite DAH requires the presence of all three of the following: (1) respiratory failure requiring supplemental oxygen or noninvasive or invasive ventilation; (2) evidence of bilateral pulmonary infiltrates on chest x-ray or chest CT; (3) the presence of progressively hemorrhagic return with serial aliquots on BAL and ≥20% hemosiderin-laden macrophages on cytopathology.[84] Probable DAH is defined by the presence of (1) and (2) above and *either* one of the criteria in (3). In a recent single-center retrospective review of 99 HSCT recipients with DAH, 39% met criteria for definite and 61% for probable DAH.[85] In the latter group, 40% had progressive bloody return on BAL and 60% met cytologic criteria, highlighting the importance of sending the latter study in order to capture patients without the classic findings at time of bronchoscopy. Two limitations to these diagnostic criteria should be kept in mind. First, hemosiderin-laden macrophages do not appear for 24 to 72 h after an acute bleed. Second, these criteria lack specificity and, in particular, do not distinguish bland DAH due to acute lung injury from DAH triggered by underlying infection.[84]

Incidence and Time Course The existing evidence base for DAH is limited, and many case series do not follow clear or consistent diagnostic criteria. Indeed, some do not even require bronchoscopic confirmation, but merely clinician suspicion of DAH based on clinical and radiographic features.[86] As such, there has been wide variability in the reports of DAH frequency after HSCT, ranging from 2% to 14% depending on criteria used.[87] However, these series include studies where DAH definition was questionable, as well as historic studies that likely do not reflect contemporary DAH epidemiology. A recent review of 4350 HSCT recipients who underwent HSCT at a single center found that 99 patients had clinical, radiographic, and bronchoscopic evidence of DAH, representing a frequency of 2.3%.[85]

Early studies indicated that the onset of DAH was most common in the first 30 days after HSCT.[87] However, DAH also can occur as a later complication of HSCT, and more recent studies suggest that the time to DAH development is longer than what was previously reported.[85,88] In the recently published cohort of 99 DAH cases, the median time to DAH identification after transplant was 126 days. The finding that DAH is encountered later in the post-HSCT period may reflect the overall improvement in peritransplant care, including better antimicrobial prophylaxis, improved identification and treatment of infectious syndromes, and improvements in the management of critical care syndromes, such as sepsis and ARDS. Many of the early-onset DAH cases seen in historic reports may have been infection-related and, as these complications have reduced, there has been a shift toward developing DAH later after HSCT.

Risk Factors High-quality epidemiologic studies evaluating risk factors for developing DAH are lacking. Pretransplant radiation (either total body irradiation for conditioning or history of thoracic radiation), higher-intensity chemotherapy/conditioning regimens, older age at transplant, and severe GVHD have been associated with DAH.[88–93] The majority of patients with DAH have thrombocytopenia, but DAH is not corrected by platelet transfusion.[85,87,93] Although some data are conflicting, DAH appears to be more common after allogeneic HSCT than autologous HSCT with up to a sevenfold increase in some reports.[85-87,93] Pretransplant PFTs do not appear to have any association with DAH development.[93]

In those who develop DAH, risk factors for mortality include a longer time from HSCT to DAH development, need for invasive mechanical ventilation, thrombocytopenia, and elevated INR. It is possible that those who develop DAH later after HSCT have additional complications such as disease relapse and GVHD that affect both the ability to withstand the course of critical illness and the aggressiveness of care options chosen.

Pathogenesis The pathogenesis of DAH in the HSCT recipient is not known. Lung injury, inflammation, and cytokine release are implicated but meaningful mechanistic studies are lacking.[87] Pretransplant chemotherapy, radiation, and infections may be responsible for the initial lung injury, and subsequent "second hits" may predispose patients to the DAH syndrome. Indeed, several autopsy studies of DAH show diffuse alveolar damage indicating there may be a component of bland hemorrhage complicating diffuse lung injury.[85,91,94]

Inflammation may play a role in the development of DAH. In one study, 123 patients underwent bronchoscopy with BAL before HSCT. Those who went on to develop DAH (14 in this series) had higher neutrophil counts in BAL. It was hypothesized that bronchial inflammation preceded alveolar inflammation and subsequent alveolar hemorrhage.[95,96] However, this is ultimately speculative. As indicated above, autopsy studies do not typically show extensive inflammation or alveolitis. However, in many of these reports there can be considerable time between DAH development to autopsy, and lung pathology findings could evolve over time from the initial DAH diagnosis. Obtaining transbronchial or surgical lung biopsies in this setting is typically not possible due to both coagulopathy and degree of respiratory failure. It is not known if GVHD is a major contributing factor to DAH development, but patients with GVHD are more likely to develop DAH.[88] Many patients with DAH have concomitant respiratory infection, with 43% having a presumed pathogenic organism identified in a recent series. Of those with infection, the majority (54%) had fungal infection.[85]

Clinical Findings Patients with DAH have nonspecific symptoms, most commonly dyspnea and cough.[87,93] Hemoptysis is rare, occurring in less than 15% of cases.[85,90,93,97] In recent reports, about 50% of patients required mechanical ventilation at the time of diagnosis while less than 10% were on room air.[85] Patients may have other coexistent post-HSCT respiratory failure syndromes such as ARDS and PERDS, emphasizing that these syndromes may have overlapping pathophysiologic underpinnings.[9]

Diagnostic Evaluation DAH is a syndrome with nonspecific clinical and radiologic features.[87] Chest radiograph shows diffuse interstitial and alveolar infiltrates, primarily central, and involving predominantly lower and middle lung zones.[98] The earliest radiographic manifestation is the presence of bilateral fine reticular opacities. In the later phase of DAH, 70% of patients develop an alveolar pattern, and the interstitial pattern persists in 30%. Although chest CT may be helpful in patients in whom a focal source of bleeding is suspected, chest CT has a limited role in DAH. The most common CT finding is bilateral ground-glass attenuation or consolidation.[99] Bronchoscopic evaluation is the cornerstone of diagnosis, and all patients who undergo BAL after HSCT should have serial aliquots performed and examined for the presence of progressively hemorrhagic return. In addition, all samples should undergo cytopathologic evaluation for hemosiderin-laden macrophages. It is also important to send microbiologic studies to assess for the possibility of an infectious trigger for DAH.

Treatment The practice of prescribing high-dose corticosteroids (often ≥1 g methylprednisolone daily) is extrapolated from the treatment of alveolar hemorrhage from immune-mediated conditions such as anti–glomerular basement membrane disease.[100] Although corticosteroid therapy is the standard of care for patients with post-HSCT DAH, consistent evidence of benefit is lacking.[92,100,101] There are no prospective, randomized clinical trials addressing the treatment of DAH in HSCT recipients.

In a retrospective observational study from the 1990s, 12 patients who received no steroids were compared with 10 patients who received low-dose steroids (30 mg methylprednisolone or less) and 43 patients who received higher-dose steroids (>30 mg methylprednisolone). The mortality rate was lower and fewer patients required invasive mechanical ventilation in the high-dose methylprednisolone group.[101] However, more recent data are equivocal. In a retrospective series of 119 HSCT patients with possible DAH, patients were divided into those who received low-dose, medium-dose, and high-dose steroid therapy.[86] Those patients with low-dose (<250 mg/d methylprednisolone) steroid therapy demonstrated improved outcomes compared to those with medium-dose (250–1000 mg/d methylprednisolone) or high-dose (>1000 mg/d methylprednisolone) steroid therapy. However, this series was limited by the nature of DAH case definition. The authors included those patients who had a diagnosis of DAH based on clinician impression, sometimes without supporting bronchoscopy data. All studies are retrospective, observational, and with high risk of bias. Although evidence remains weak, given the lack of effective therapeutic options and grave overall prognosis, corticosteroids remain standard of care for patients with DAH after HSCT. However, moderate-dose corticosteroids (e.g., 125 mg or 250 mg methylprednisolone) may be adequate in lieu of the very high doses that are often prescribed.

In addition to corticosteroids, it is reasonable to provide blood product support to reverse any coagulopathy. However, this has not been associated with improved outcomes.[102] Some groups have also advocated the use of aminocaproic acid in this setting, but evidence for benefit is again lacking.[86] Given that the risks of aminocaproic acid are low, this may be a reasonable option to consider. There are reports of allogeneic HSCT recipients with DAH treated with recombinant factor VIIa,[94,103,104] but this cannot be routinely recommended.

Prognosis DAH is a major complication of HSCT, contributing significantly to morbidity and mortality. The majority of HSCT recipients with DAH require mechanical ventilator support for respiratory failure.[87] The reported mortality rate of DAH in historic series was close to 80%.[87] More recent series suggest that the mortality rate may be closer to 60%, lower than previous reports but still unacceptably high.[85,105] Although the initial presentation of DAH in HSCT recipients may be with respiratory failure, the most common causes of death are multiple organ failure and sepsis. Respiratory failure with active pulmonary hemorrhage is responsible for fewer than 15% of the deaths.

Idiopathic Pneumonia Syndrome

IPS is an umbrella term for lung injury without an infectious etiology in HSCT recipients. It was first described in 1985 as idiopathic pneumonia in a review of pulmonary complications of 4500 HSCT recipients.[12,106] Diagnostic criteria were initially addressed in 1993 by a workshop sponsored by the National Heart, Lung, and Blood Institute.[107] This workshop defined IPS as widespread alveolar injury and hypoxemic respiratory failure in the absence of lower respiratory tract infection.[10,107] The criteria were updated in 2011 to additionally require exclusion of cardiac dysfunction, renal failure, and iatrogenic volume overload as the etiology for pulmonary dysfunction.[10]

Frequency The incidence of IPS varies between 2% and 17% across studies.[10,108–117] The most recent large epidemiologic study of IPS reported an incidence of 3.7% in a cohort of 1829 HSCT patients.[42]

Similarities with ARDS IPS is similar to ARDS in its clinical presentation and management. The key differences are (1) ARDS requires an inciting event within 7 days of syndrome development, whereas IPS does not; (2) ARDS has specific requirements with regard to the magnitude of hypoxemia (Pa_{O_2}/Fi_{O_2} ratio <300 mm Hg) and ventilatory support (invasive or noninvasive ventilation requiring positive end-expiratory pressure >5 cm H_20); and (3) IPS requires that infection has been excluded, whereas ARDS encompasses both infectious and noninfectious lung injury. IPS and ARDS share the common criteria that diffuse bilateral pulmonary infiltrates must be present, and the clinical syndrome should not be fully explained by cardiac failure or fluid overload.[118] Patients with IPS and ARDS can both have diffuse alveolar damage on histology.[10] Given the similarities and overlapping features noted, the principles of ARDS management can be extrapolated to management of IPS.

Risk Factors Several risk factors have been associated with IPS.[42,116] Allogeneic transplant, myeloablative conditioning therapies, use of total body irradiation for conditioning, and the presence of GVHD have all been associated with increased IPS risk.[42,119] Patients with poorer pretransplant pulmonary function are at increased risk of IPS development.[42] Patients transplanted for aplastic anemia typically have a lower risk for IPS.[120] CMV status (recipient and donor), HLA matching, and underlying malignancy do not appear to alter IPS risk.

Pathogenesis Although the pathogenesis of IPS is not well defined, lung injury, inflammation, and cytokine release are all implicated.[119] Pulmonary vascular endothelial cell damage, mediated by tumor necrosis factor (TNF)-α, is linked to the development of IPS in experimental animal models.[10,121] The occurrence of IPS after autologous BMT suggests that the pretransplant conditioning regimens, rather than GVHD and CMV infection, are likely to be culprits.[93] Similar to ARDS, infections and systemic activation of inflammatory cytokines during sepsis may also be responsible for lung injury.[111,122–125] Cell-mediated immune injury during GVHD and free-radical oxidant-mediated injury also have been hypothesized as contributing factors.[111,126,127]

Clinical Findings and Evaluation The median time to IPS onset is typically within 30 days of HSCT, and most patients will develop the syndrome within 120 days.[10,42,111,112] In a recent large cohort series, the median time to IPS onset after allogeneic HSCT was 25 days (range, 4–118 days).[42] Clinical features include dyspnea, dry cough, hypoxemia, and nonlobar radiographic opacities.[107] The spectrum of severity is broad, ranging from acute respiratory failure to incidental radiographic abnormalities.

Because IPS mimics infectious pneumonia, most patients receive antibiotics and evaluation for infection is routine. If permitted by the patient's respiratory status, bronchoscopy is performed to exclude infection and to evaluate for DAH. When pursued, lung biopsies of patients with IPS show diffuse alveolar damage, organizing or acute pneumonia, and/or interstitial lymphocytic inflammation.[110,111]

Treatment The treatment of IPS is primarily supportive.[55] The majority of patients require invasive ventilation,[128] and low stretch protocols similar to those employed in ARDS should be utilized. There is little evidence supporting any specific pharmacotherapies. Several groups have reported experience with corticosteroids. While some small series suggested benefit,[110,129] larger series did not.[109,128] Despite lack of evidence of benefit, most patients with IPS receive a trial of corticosteroids. Dosing is not clearly established and ranges from 1–4 mg/kg/day of methylprednisolone.[42]

Based on the observation that patients with IPS tend to have high cytokine expression in BAL, there was substantial interest in TNF-α inhibition with etanercept, usually in conjunction with corticosteroids.[10,130–133] This was ultimately evaluated in a randomized clinical trial in which 34 patients with IPS were randomized to receive either corticosteroids (2 mg/kg/d methylprednisolone) with etanercept (0.4 mg/kg twice weekly × 4 weeks) or corticosteroids alone.[134] There was no observed benefit with the addition of etanercept. Of note, this trial fell substantially short of planned enrollment (120 patients) and as such may have been underpowered to detect any differences. Although etanercept continues to be prescribed in patients with IPS, its use is not supported by any evidence. While lung transplant offers a potential therapeutic option for patients, reports are rare.[135]

Prognosis Early studies reported mortality rates between 60% and 86%, with a 1-year survival of less than 15%.[111,112,116,117,120,136] Many of those who develop IPS develop nonpulmonary organ failure that contributes to the high mortality rate.[111,136] There is some indication that the overall prognosis has improved in recent years.[42,133,134] For example, a recent series reported those who developed IPS had a mortality rate of 46% within 120 days of HSCT and 30% of patients with IPS were alive at 1 year post-HSCT.[42]

■ Late, Noninfectious Pulmonary Complications

Late-onset noninfectious pulmonary complications of HSCT are a major contributor to long-term morbidity and nonrelapse mortality in HSCT survivors who may otherwise be cured of their underlying hematologic disease. Although the definition is variable, any process occurring more than 100 days after HSCT typically is considered a late-onset complication. Bronchiolitis obliterans is the best recognized long-term complication, but there is increasing recognition of a wide spectrum of persistent pulmonary disease post-HSCT that includes pleural disorders and interstitial lung disease.

Bronchiolitis Obliterans

Bronchiolitis obliterans (BO) is an inflammatory and fibroproliferative process primarily affecting the small airways that leads to the development of airflow limitation.[137,138] The term *bronchiolitis obliterans syndrome (BOS)* is used when there are clinical, radiographic, and physiologic features of BO in the absence of histologic proof. BO is a common and problematic complication that is seen exclusively in allogenic HSCT recipients.

Frequency Since histopathologic confirmation is uncommon, the majority of series report the incidence of BOS instead.[49] The incidence of BOS after allogeneic HSCT approximates 5% based on pooled estimates from multiple series, although there is substantial heterogeneity in this estimate.[22,23,139–142] The median time to diagnosis is between 6 months and 1 year, and most patients who develop the disease are diagnosed within 2 years of HSCT. Importantly, these series may underestimate the true incidence. Patients who have mild disease may be asymptomatic and may not have CT imaging or PFTs performed (measurement bias). Transient declines in FEV_1 are common in the first 6 months post-HSCT, and typically the diagnosis of BOS is not made until at least 3 months have elapsed after HSCT. This can introduce implicit survival bias. Lastly, the NIH consensus diagnostic criteria proposed for BOS have good specificity but relatively low sensitivity.[143,144] As such, they may underestimate the incidence of BOS after HSCT.

Risk Factors Several risk factors for development of BOS have been identified, predominantly in retrospective studies, sometimes with conflicting results.[119,145] The one risk factor shared across all studies is concomitant extrathoracic chronic GVHD.[21,23,44,140,141,146–149] For example, in a series of 63 BOS patients in a cohort of 1145 allogeneic HSCT recipients, 100% of patients had chronic GVHD.[22] However, this also may be a reflection of bias, as the BOS diagnosis may be considered only in patients with preexisting GVHD. Other

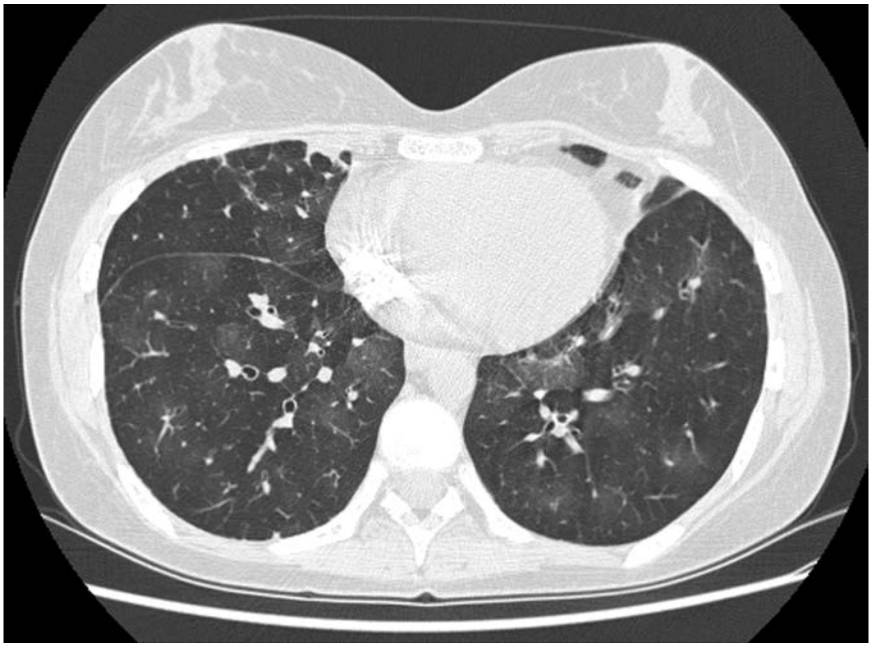

Figure 94-2 Computed tomography scan with expiratory views of a patient with bronchiolitis obliterans following hematopoietic stem cell transplantation. Mosaic attenuation associated with of air trapping (darker areas), bronchial thickening and mild bronchiectasis are evident.

risk factors identified across various studies include older age of both donor and recipient, busulfan-based conditioning, a time from disease diagnosis to transplant of 14 months or longer, methotrexate use, peripheral blood stem cell source, transplant from female donor to male recipient, and acute GVHD.[21,23,44,140,141,146–149] While pulmonary infections are common in patients with BOS, it is not clear whether they are causally related or result from associated immunodeficiency. Factors identified as potentially protective for BOS development include T-cell depletion with antithymocyte globulin and use of cord blood for the donor.[148–151]

Pathogenesis Little is definitively known about the pathogenesis of BO, although the strong association with GVHD suggests a shared pathogenesis. Early in the syndrome, bronchiolar inflammation can be seen.[152,153] Specifically, it is hypothesized that in response to some injury mechanism (e.g., chemotherapy, radiation therapy, infection) there is lymphocyte inflammation around small vessels and the respiratory epithelial lining of the small airways, followed by epithelial cell necrosis and mucosal denudation.[147] The association between BO and chronic GVHD has led to the hypothesis that host bronchiolar epithelial cells serve as a target for donor cytotoxic T lymphocytes, a hypothesis supported by the relative absence of BOS in T cell–depleted grafts.[151,154] Although a CD8 T-cell response appears to be important in pathogenesis, B-cell and humoral immune mechanisms also are likely required. In an animal model of post-HSCT BO, mice incapable of secreting IgG alloantibodies demonstrated substantial reductions in both BO and GVHD.[155] Alternative explanations for BOS development include recurrent aspiration of oral material due to esophagitis associated with GVHD, abnormal local immunoglobulin secretory function in the lungs, and unrecognized infection.[154,156] The variations in histopathology, bronchoalveolar cell differential, clinical course, and frequency of associated pulmonary infection suggest that the pathogenesis is multifactorial.[154,157] BOS in HSCT recipients resembles chronic allograft rejection in lung transplant recipients at immunologic, pathologic, and physiologic levels.[25] Similar to the mechanisms outlined above, T cell–mediated recognition of alloantigens expressed in the lung tissue plays a central role.[147]

Clinical and Radiographic Features The clinical features of BOS are nonspecific and include dyspnea, cough, exercise intolerance, and wheezing.[24,158,159] However, as many as 20% of patients with BOS lack respiratory symptoms at the time of the first abnormal pulmonary test.[160] Wheezing can be detected on physical examination in about 40% of patients.[24]

Chest radiographs are usually normal or may show hyperinflation.[24,25,161–163] Inspiratory and expiratory HRCT should be included as part of the evaluation process for BOS.[160] HRCT typically shows mosaic attenuation due to air trapping (most pronounced on expiratory images), often accompanied by vascular attenuation, bronchiectasis, and bronchiolectasis (Fig. 94-2).[25,162,164–166]

Diagnosis The diagnosis of BO is based on histologic evaluation of lung tissue demonstrating bronchiolar wall thickening, fibrosis, and narrowing of the airway lumen (Fig. 94-3).[25,152,159,167,168] Peribronchiolar inflammatory cellular infiltrates consisting of neutrophils and lymphocytes may be present.[169] Given that transbronchial lung biopsies rarely contain sufficient bronchiolar tissue to establish a histologic diagnosis and that surgical lung biopsy is invasive and carries substantial procedural risk, most patients are diagnosed based on the clinical, radiographic, and physiologic criteria for BOS. Diagnostic criteria for BOS were established by the National Institutes of Health (NIH) in order to standardize enrollment for clinical trials (Table 94-4).[144] The advantage of these criteria is that they can be satisfied with a noninvasive evaluation consisting of CT scan and PFTS, as long as the patient has no clinical evidence of respiratory infection and has at least one other organ system affected by chronic GVHD. On the other hand, the requirement that in the absence of extrathoracic GVHD, a surgical lung biopsy is required for diagnosis is impractical and unnecessary in most clinical settings. Furthermore, the sensitivity of these criteria is too low for clinical use.[170] Many patients with BOS may not meet all these criteria and such stringent criteria may miss those in the early stage of the disease when diagnosis may be most important.

The particular set of normative values utilized in interpretation of PFTs also can have a significant impact on the ability of these criteria to detect cases. In one study, utilization of the National Health and Nutrition Examination Survey (NHANES) III normative values in place of an older system increased the percentage of allogeneic HSCT recipients who met BOS criteria from 17% to 25%.[171] Ongoing research is needed to determine earlier, more sensitive, and more specific markers of BOS development. Monitoring decline in FEV_1 with routine post-HSCT PFT screening may be of value in early diagnosis.[172,173]

Based on the magnitude of decline in FEV_1, BOS is classified into stages: stage 1 (FEV_1 66%–80% of peak posttransplant baseline), stage 2 (FEV_1 51%–65% of baseline), and stage 3 (FEV_1 <50% of baseline).[174] This classification scheme was initially developed exclusively for lung transplant recipients and has not yet been widely applied to the HSCT population. Thus, its utility in defining severity or prognosis in this population remains to be established.

Treatment No therapy has been shown to be effective for the treatment of BOS, and the predominant focus of treatment is to prevent further declines in lung function.[137,145,147] Extrapolating from the treatment of chronic GVHD, the standard initial therapy for BOS

TABLE 94-4 National Institutes of Health Consensus Clinical Definition of Bronchiolitis Obliterans Syndrome After Hematopoietic Stem Cell Transplantation (2005)

Pulmonary function testing	$FEV_1/FVC < 0.70$ *and* $FEV_1 < 75\%$ predicted *or* $RV > 120\%$
Imaging	Evidence of air trapping or bronchiectasis on lung computed tomography
Demonstrated graft-versus-host disease	Chronic graft-versus-host disease in another organ system *or* Lung biopsy demonstrating changes compatible with bronchiolitis obliterans
Evaluation for infection	Acute changes not attributable to an acute infectious process

FEV_1, forced expiratory time in 1 s; FVC, forced vital capacity; RV, residual volume.

Data from Filipovich AH, Weisdorf D, Pavletic S, et al. National Institutes of Health consensus development project on criteria for clinical trials in chronic graft-versus-host disease: I. Diagnosis and staging working group report. Biol Blood Marrow Transplant. 2005;11(12):945–956.

is with systemic corticosteroids. Some patients may already be on immune suppression for preexisting GVHD. Prednisone 1 to 1.5 mg/kg/d, or its equivalent, is given for 4 to 6 weeks. If respiratory status remains stable, therapy is tapered and discontinued over several months. While several series have reported outcomes with steroids (often coupled with other medications), there have been no controlled trials, and evidence for efficacy of corticosteroids in BOS is lacking.[24,25,147,162,166,175,176] Immunosuppressive steroid-sparing drugs such as cyclosporine, tacrolimus, and mycophenolate mofetil also are used in BOS, but again this is limited to uncontrolled series without meaningful evidence for benefit.[47,137,145,154,177] Several other therapies have been studied for BOS, and the experience with these is outlined below.

Macrolides have immunomodulatory effects, and it has been hypothesized that this may halt disease progression in BOS.[81] Based on small studies in post-HSCT BOS, there was substantial interest in azithromycin specifically.[177] However, a subsequent meta-analysis of these studies suggested no benefit of azithromycin for the treatment of BOS.[178] To evaluate whether azithromycin may prevent BOS, the ALLOZITHRO trial randomized 480 allogeneic HCT patients to either placebo or three-times-weekly azithromycin at the time of conditioning chemotherapy.[179] These results showed substantial harm from macrolide therapy in the treatment group. Those receiving azithromycin had worse airflow decline–free survival, increased rate of hematologic relapse, and worse overall survival than placebo. As a result of these data, many centers no longer routinely administer azithromycin for the prevention of BOS.

Part of the drug "cocktail" that was initially studied in BOS alongside azithromycin included the inhaled corticosteroid (ICS) fluticasone and the leukotriene antagonist (LTA) montelukast, collectively termed FAM.[180] The rationale was to combine anti-inflammatory effects (ICS), immunomodulation (macrolides), and theoretical antifibrotic effects (LTA).[181] Multiple small observational studies suggested that ICS and LTA (either combined or in isolation) may have a role in stabilizing or even improving FEV_1 in patients with BOS.[180,182–185] However, these studies had substantial methodologic limitations and high risk of bias. Based on the limited data supporting its efficacy, montelukast is not routinely recommended for patients with BOS. A clinical trial evaluating ICS enrolled 32 patients with BOS, randomizing patients to either budesonide/formoterol or placebo for 6 months. The primary endpoint was change in FEV_1 at 1 month. This study found that the median FEV_1 increased by 260 mL in the budesonide/formoterol arm compared with 5 mL in the placebo arm ($p = 0.012$), and this improvement was sustained for 6 months in the 13 of 25 patients who received ICS. Although promising, conclusions from this study are limited due to small sample size and substantial crossover between treatment and placebo arm. Nonetheless, combination ICS/LABA should be considered in patients with BOS.

A promising emerging therapy for BOS is extracorporeal photopheresis (ECP). In this procedure, white blood cells are removed through apheresis and exposed to ultraviolet radiation after pretreatment with a psoralen derivative, leading to T-cell death. ECP was initially developed for the treatment of cutaneous T-cell lymphoma and adapted to chronic severe GVHD.[186] In a literature review of 735 patients with steroid-resistant, steroid-intolerant, or steroid-dependent chronic GVHD, ECP resulted in response rates of 50% to 65%, and complete response in 30% to 35% of patients.[187] Between 25% and 35% of patients were able to taper or discontinue systemic steroids. Several observational studies have reported potentially favorable results with ECP.[186,188,189] In one multicenter observational study, 26 patients with BOS who underwent at least 3 months of ECP were propensity matched 1:1 with 26 patients with BOS who did not undergo ECP.[19] The group undergoing ECP had improved overall survival, improved functional status (as measured by Karnofsky score), and lower corticosteroid use compared with non-ECP controls. However, the two groups did not differ in any pulmonary function test parameters. This may indicate that survival benefit conferred by ECP is independent of PFT measures, and the corticosteroid-sparing effect may be responsible for the improved survival. To better determine the role of ECP in this setting, a phase 2 clinical trial of ECP in steroid-refractory GVHD is currently underway (NCT03007238).

ECP is a relatively specialized procedure and may not be available in all centers. The regular need for apheresis means patients will require long-term indwelling central venous access. Given targeted T-cell depletion, patients should be considered immunosuppressed. Until further data are available, ECP is a reasonable therapy to consider for patients with severe BOS after HSCT, especially if there is concomitant steroid-refractory, extrathoracic GVHD.

Another emerging therapy for BOS is the Janus kinase (JAK) inhibitor ruxolitinib. JAK signaling is thought to be important in the pathogenesis of both acute and chronic GVHD.[190] A phase 3, randomized, controlled trial compared ruxolitinib to standard care in patients with steroid-dependent or steroid-refractory GVHD. Patients receiving ruxolitinib had significantly greater overall response to GVHD treatment (49.7% vs. 25.6%; odds ratio [OR], 2.99; $p < 0.001$) and symptom control (24.2% vs. 11.0%; OR, 2.62; $p = 0.001$) than controls.[191] However, response to patients with BOS was poor in both groups: 8.6% response in the ruxolitinib group and 6.1% in the control group. This highlights that BOS may be particularly difficult to treat within the post-HSCT GVHD spectrum.

Other therapies considered for BOS include TNF blockade[192] and the anti-CD20 monoclonal antibody rituximab.[193,194] Experience with these is limited to case reports and case series. The novel antifibrotic agents pirfenidone and nintedanib are being studied for BOS, but definitive data are not yet available.

Lung transplantation may be considered for patients with far-advanced BOS who are otherwise deemed to have a successful HSCT without risk of relapse of the underlying disease process. Published experience to date is largely limited to case reports.[135,195–200] In a cross-sectional study of 313 lung transplant recipients, 3 were performed for BOS in allogeneic HSCT recipients.[199] Lung transplants utilizing living donors have also been reported in this setting, but this procedure is currently rarely performed.[197,200,201]

Prognosis The clinical course of BOS is highly variable. The majority of patients have initial worsening of pulmonary function over 6 months, followed by stabilization.[202] Few patients have improvement in FEV_1 after diagnosis—likely less than 20%. The long-term trajectory of pulmonary function 1 year after diagnosis shows a rate of decline that exceeds normal aging, but is similar to an adult patient with COPD.[202] A more rapid initial worsening of pulmonary function may be associated with poor outcome.[24] Unfortunately, while pulmonary function tests can stabilize, the diagnosis of BOS is associated with considerable morbidity and mortality. Survival in historic series was poor, with 65% dying within 3 years of diagnosis.[23,140,160,176,192] However, more recent series suggest a 2-year survival of 70% to 80%, possibly due to better recognition, improved treatment of infection, and improved supportive care when critically ill.[19,202]

Organizing Pneumonia

Bronchiolitis obliterans organizing pneumonia (BOOP) had been widely recognized since Epler introduced the term in 1985.[203] The American Thoracic Society/European Respiratory Society recommended replacing BOOP with cryptogenic organizing pneumonia (COP) since it better describes the essential features of the syndrome.[204] Since organizing pneumonia (OP) is felt to be a complication of HSCT, the term cryptogenic is typically not used. OP in HSCT patients was first reported in the early 1990s,[205,206] and literature is largely limited to case series.[12,139,152,162,205–216] Risk factors for OP are not well described, although there is some evidence that it represents an atypical form of GVHD.[207,212,214]

Pathogenesis The occurrence of OP almost exclusively in allogeneic HSCT recipients with GVHD suggests that it may represent alloimmune-mediated injury to the lung.[160,202,210] However, OP has been reported in allogeneic HSCT recipients in the absence of clinical GVHD, suggesting that other mechanisms are involved as well.[205,217] There is a single report suggesting that recipient human leukocyte antigen (HLA) B35 may be a factor in pathogenesis.[218]

Clinical Features The presenting symptoms are nonspecific and include dry cough, dyspnea, and fever.[205–207,212] Some patients may present with respiratory failure.[214] The reported onset of OP is highly variable, ranging between 1 and 13 months following transplant in published series.[162,205–207,211,213,215,217,219]

Diagnostic Evaluation OP should be included in the differential diagnosis of bilateral airspace disease in HSCT recipients, especially if they do not respond to antibiotics for presumed pneumonia. Pulmonary function tests usually show a restrictive defect, decreased D_{LCO}, and normal airflow.[203,206,207] Chest radiographs and CT show patchy air space consolidation, ground glass attenuation, and nodular opacities.[99,163,205–208,220] The radiographic abnormalities usually demonstrate a peripheral distribution.[221] While chest CT findings may be suggestive of OP, confirmation requires lung biopsy. The yield of transbronchial lung biopsy is relatively low, and VATS lung biopsy is often required if definitive diagnosis is deemed essential.[207] The histologic hallmark of OP is the presence of patchy intraluminal fibrosis, consisting of polypoid plugs of immature fibroblast tissue resembling granulation tissue.[222]

Treatment Corticosteroid therapy is the treatment of choice, with reported response rates approximating 80%.[162,205–207,211,213,215,219]

Radiographic abnormalities usually clear within 1 to 3 months of initiating corticosteroids.[205,207,213] Based on the experience from non-HSCT recipients with OP, prednisone at a dose of 0.75 to 1.5 mg/kg/d, or equivalent, is typically administered for 1 to 3 months, followed by lower doses for a total duration of 6 to 12 months.[223] While typically steroid-responsive, there is a significant risk of relapse as steroids are tapered below 10 to 15 mg daily.

Prognosis OP in HSCT recipients appears to have a worse prognosis than COP in non-HSCT populations. Alasaly et al. found a case fatality rate of 40% in allogeneic HSCT recipients compared with 21% in COP.[207] Among 19 reported HSCT recipients with OP documented in other published reports, the overall case fatality rate was 21%.[162,205–207,211,213,215,217,219]

Interstitial Lung Disease

Interstitial lung disease after HSCT may represent atypical manifestations of GVHD, sequelae of prior chemotherapy and radiation therapy, or sequelae of prior lung injury (e.g., ARDS, IPS, DAH). Several of these entities are discussed below.

Pleuroparenchymal Fibroelastosis Pleuroparenchymal fibroelastosis (PPFE) is a rare interstitial lung disease characterized by upper lobe–predominant pleural and subpleural parenchymal fibrosis[224] with minimal inflammation. PPFE has been described in several populations and was first reported in HSCT recipients in 1991.[225] In a radiology-based review of 700 HSCT patients, 2 patients met criteria for PPFE, suggesting that this is a rare complication in this patient population.[226] Pulmonary function testing typically shows a restrictive pattern in the absence of underlying lung disease.[226] Diagnosis is principally based on presence of the characteristic radiographic features of bilateral apical fibrosis with adjacent pleural thickening. Prognosis is typically felt to be poor, although overall experience is limited. The pathogenesis of PPFE is unclear. Given that it is also seen as a manifestation of lung allograft rejection in lung transplant recipients, it may represent another atypical form of alloimmune-mediated GVHD. Supporting this, case reports of PPFE histology often demonstrate concurrent presence of BO.[225,227,228]

Pulmonary Alveolar Proteinosis Pulmonary alveolar proteinosis (PAP) is characterized by excessive accumulation of surfactant lipoprotein in the alveoli, leading to abnormal gas exchange.[229] It is diagnosed by the presence of periodic acid–Schiff proteinaceous material in BAL fluid and in alveolar air spaces on transbronchial lung biopsies. The occurrence of secondary PAP in HSCT recipients is rare but has been documented in case reports.[230–233] Chest radiograph and CT show characteristic diffuse ground glass infiltrates. The roles of whole lung lavage and aerosolized granulocyte-macrophage colony-stimulating factor, therapies employed in the primary autoimmune form of PAP, are not well established in the secondary form seen in HSCT recipients.

Chronic Eosinophilic Pneumonia There are rare case reports of chronic eosinophilic pneumonia occurring in both allogeneic and autologous HSCT recipients.[234–237] Response to corticosteroid therapy was favorable in most case reports, although there is a single report of a patient with a fatal course.[236]

■ Pulmonary Vascular Disorders

Pulmonary vascular disorders complicating HSCT are discussed briefly below.

Pulmonary Cytolytic Thrombi

Pulmonary cytolytic thrombi (PCT) is a noninfectious pulmonary complication of HSCT recipients occurring predominantly in children.[238,239] PCT occurs almost exclusively in patients with acute or chronic GVHD and is characterized by fever and pulmonary nodules. The time of onset ranges from 8 to 343 days (median, 72) after transplant.[239] Chest radiographic findings include nodules, interstitial prominence, and atelectasis. Chest CT shows multiple peripheral pulmonary nodules, ranging from a few mm to 4 cm in size.[238–241] Bronchoscopy is typically performed to exclude infection. Because of the peripheral and intravascular location of the nodules, transbronchial lung biopsy is unlikely to yield a diagnosis. Among 33 HSCT recipients who underwent open lung biopsy for nodular pulmonary lesions, 15 (45%) had PCT.[241] Biopsy of the pulmonary nodules shows a unique pattern of necrotic, basophilic thromboemboli with amorphous material suggestive of cellular breakdown products.[240,242] Most patients with PCT have a self-limited course without specific treatment, improving clinically within 1 to 2 weeks. Radiographic improvement typically occurs over weeks to months.[239] There have been no reported deaths attributed to PCT. In one study, 9 of the 13 HSCT recipients with PCT were alive at a median follow-up of 1.5 years.[239] All patients received broad-spectrum antibiotics and 9 were treated with systemic corticosteroids.[239]

Pulmonary Veno-occlusive Disease

Pulmonary veno-occlusive disease (PVOD) is a rare pulmonary vascular complication of HSCT with high morbidity and mortality. It should be suspected in patients with dyspnea, evidence of pulmonary hypertension in the absence of left heart failure, and imaging suggestive of pulmonary edema. Although the clinical picture is suggestive, definite diagnosis requires lung biopsy. The incidence of PVOD in HSCT recipients is not known but is likely extremely rare. Existing reports are limited to case series.[49,243] Endothelial damage from conditioning chemotherapy, radiation therapy, and certain chemotherapy agents (bleomycin, mitomycin, and carmustine [BCNU]) have been hypothesized as potentially contributing to PVOD.[244–247] There is no proven therapy for PVOD. While vasodilators are used in various forms of pulmonary arterial hypertension, they may be detrimental in PVOD. Dilating the pulmonary arterial vasculature in the setting of fixed venous resistance may precipitate pulmonary edema, leading to respiratory compromise.

SOLID ORGAN TRANSPLANTATION

This section focuses on noninfectious complications associated with the three most commonly performed solid organ transplant procedures: heart, kidney, and liver transplantation.

Noninfectious complications in lung transplant recipients are discussed in Chapter 106. Infectious complications in immunocompromised hosts, including solid organ transplant recipients, are discussed in Chapter 123.

■ Perioperative Complications

Perioperative pulmonary complications associated with liver, heart, and kidney transplantation are discussed below.

Liver Transplantation

Ventilatory support beyond 48 h is required by 25% to 36% of recipients immediately following liver transplantation.[248–250] Preoperative Model for End-stage Liver Disease (MELD) score has been identified as an important independent predictor of risk of prolonged postoperative ventilatory support, with an average MELD score of 36.4 for those with prolonged postoperative ventilator dependence.[249,250] Another study employing multivariate analysis identified the following preoperative risk factors as independently associated with an increased risk of postoperative respiratory failure following liver transplantation: diabetes mellitus, impaired renal function, preoperative ventilator support, use of a molecular adsorbent recycling system as an artificial liver support strategy, and deceased donor liver transplantation.[251] For those who are successfully extubated, reintubation at some point in the perioperative period occurs in one-third of patients who had initially required greater than 24 h of ventilatory support and 10% of those initially ventilated for less than 24 h.[248,252] Both postoperative respiratory failure and the need for reintubation are associated with significantly poorer survival.[251,252]

A number of factors contribute to respiratory failure, including impaired respiratory muscle function from extensive upper abdominal surgery, malnutrition, and debility; marked intravascular volume shifts and volume overload; aggressive blood product support; and a relatively high frequency of postoperative pneumonia. Additionally, patients undergoing liver transplantation are often critically ill at the time of transplantation and it is not unusual for patients to have been supported on mechanical ventilation for varying periods of time prior to transplantation.

Acute respiratory distress syndrome (ARDS) is a particularly lethal cause of postoperative respiratory failure following liver transplantation, with a reported incidence ranging from 4% to 16%.[253–255] In one study, three preoperative factors—encephalopathy, need for mechanical ventilation, and degree of hyperbilirubinemia—and one intraoperative factor—need for high-level pressor support—were identified as independent risk factors for development of postoperative ARDS.[254] Generic risk factors for ARDS that are commonly encountered in the liver transplant recipient include sepsis, massive blood transfusions, transfusion-related acute lung injury, and aspiration. Reported mortality rates vary, with one contemporary series documenting an 18% mortality rate at 3 months, compared to 8% for those without ARDS.[254]

Hepatopulmonary syndrome (HPS) and portopulmonary hypertension (PPH) are two pulmonary complications of advanced liver disease. Although their onset precedes liver transplantation, these disorders do not immediately or invariably correct following this intervention and they can therefore contribute significantly to morbidity and mortality intraoperatively and in the early postoperative period.

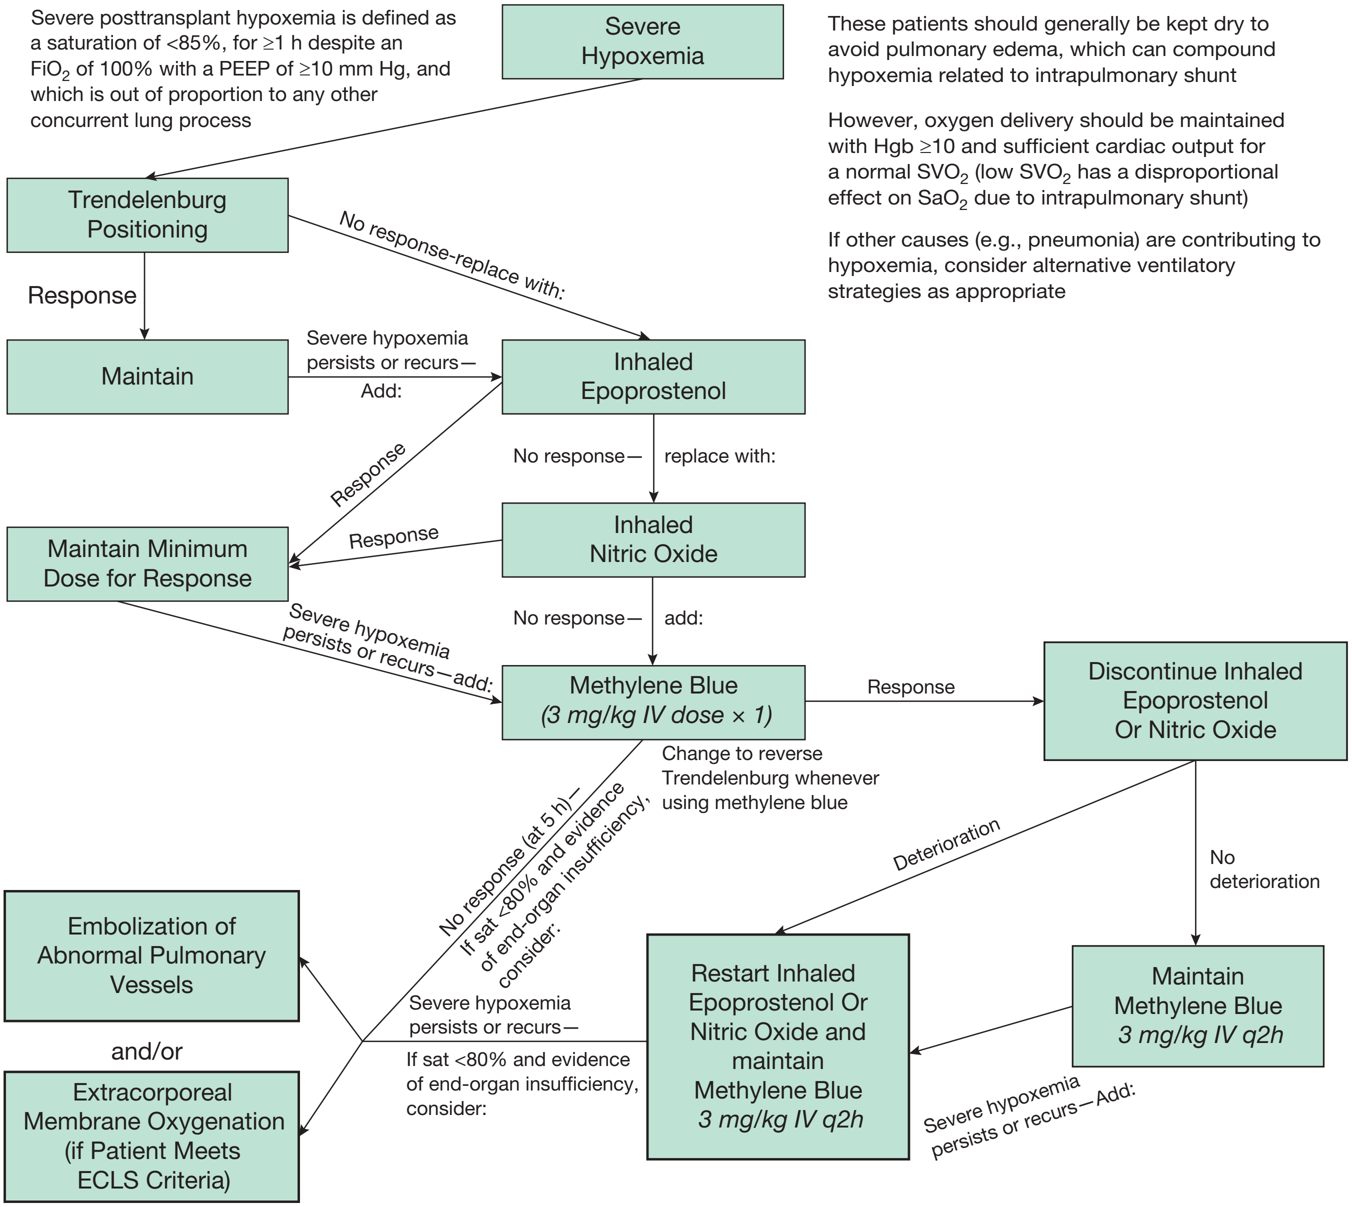
HPS is defined as the triad of liver disease, arterial hypoxemia, and abnormal intrapulmonary vascular dilatation. The vast majority of cases involve diffuse dilatation of the pulmonary microvasculature at the precapillary and capillary level. Rarely, discrete macroscopic arteriovenous communications are present. Proof of the presence of intrapulmonary vascular abnormalities is provided by demonstration of systemic uptake of technetium-labeled macroaggregated albumin on radionuclide perfusion imaging or the delayed appearance of bubbles in the left atrium by contrast echocardiography. Diffuse microvascular dilatation is postulated to cause hypoxemia by increasing the distance through which oxygen must diffuse and thereby creating a central stream of inadequately oxygenated red cells. Unlike a true shunt, this process can be partially corrected with administration of 100% oxygen, which serves to increase the pressure gradient favoring transfer of oxygen from the alveolus to the bloodstream. An unusual feature of HPS is the tendency for oxygenation to worsen in the erect as opposed to supine position (orthodeoxia), presumably due to basilar predominance of the vascular abnormalities.

Although HPS was once considered an absolute contraindication to liver transplantation, subsequent demonstration of its resolution following transplantation led to the reversal of this stance. Indeed, liver transplant candidates with severe HPS (Pa_{O_2} <60 mm Hg on room air) are granted additional MELD points and thus receive enhanced priority with regard to organ allocation. Nonetheless, because hypoxemia often does not correct immediately and may in fact dramatically worsen in the early postoperative period, excessive morbidity and mortality have been observed among these patients. In particular, severe preoperative hypoxemia (Pa_{O_2} <45–50 mm Hg on room air) has been associated with an increased risk of posttransplant mortality in multiple studies, including a multivariate analysis of the United Network for Organ Sharing (UNOS) database.[256,257] Nonetheless, contemporary case series from two experienced liver transplant centers reported no difference in mortality among those HPS patients with Pa_{O_2} <50 mm Hg compared with a less severely hypoxemic cohort.[258,259] The vast majority of patients who survive to hospital discharge ultimately achieve normal room air oxygen levels, most by 6 months following transplantation.[258] Late recurrence of HPS coincident with deteriorating allograft function has been reported.[260]

Postoperative care of the patient with persistent hypoxemia due to HPS centers on the administration of supplemental oxygen while awaiting resolution of the disorder. Based on the positional nature of hypoxemia discussed above, one group reported improvement in oxygenation in a patient with use of the Trendelenburg position.[261] With the demonstration that nitric oxide is an important mediator of the abnormal vascular dilatation that characterizes HPS, attention has turned to the potential therapeutic role of inhibitors of nitric oxide in treating hypoxemia.[262] Schenk et al. described significant improvement in oxygenation and shunt fraction for up to 10 h after administration of a single dose of methylene blue to seven patients with advanced cirrhosis and HPS.[263] Brussino et al. administered nebulized N(G)-nitro-L-arginine methyl ester—an inhibitor of nitric oxide synthesis—to a single patient with HPS and demonstrated a marked rise in arterial oxygen tension and a dramatic reduction in the magnitude of bubbles appearing in the left atrium on contrast echocardiography.[264] In contrast, administration of this agent to 10 patients with HPS did not result in an improvement in gas exchange parameters in another study.[265] Paradoxically, administration of inhaled nitric oxide can improve oxygenation in patients with posttransplant HPS, presumably by increasing perfusion to uninvolved areas of lung without increasing flow through the abnormal arteriovenous channels.[266,267] In the rare instances in which discrete arteriovenous malformations are present, coil embolization can be an effective treatment strategy.[268] Finally, successful use of extracorporeal membrane oxygenation (ECMO) for severe refractory hypoxemia due to HPS has been documented.[269] An algorithm for managing severe hypoxemia (oxygen saturation <85% despite 100% Fi_{O_2} and 10 PEEP) has been published (Fig. 94-4).[270]

PPH describes the development of pulmonary hypertension in patients with advanced liver disease and portal hypertension. The diagnosis rests on demonstration of a mean pulmonary artery pressure exceeding 25 mm Hg and a normal pulmonary capillary wedge pressure. Some authors also include the criterion of a pulmonary vascular resistance exceeding 120 $dyn/s/cm^{-5}$ to distinguish this syndrome from the more benign and common finding of elevated pulmonary pressures due solely to increased cardiac output. PPH is encountered in 1% to 2% of patients with chronic liver disease and in up to 12.5% of patients referred for liver transplant evaluation.[271]

Although mild pulmonary hypertension does not appear to adversely impact liver transplantation, more significant elevations in pressure are associated with excessive posttransplantation mortality. A retrospective review from the Mayo Clinic and a subsequent multicenter database documented perioperative mortality rates of 0% to 17% among liver transplant recipients with a preoperative mean pulmonary artery pressure below 35 mm Hg. In contrast, perioperative mortality rates were 35% to 40% for patients with a mean pulmonary artery pressure of 35 to 50 mm Hg and 40% to 100% for those with a mean pulmonary artery pressure exceeding 50 mm Hg.[272,273] Most deaths occur intraoperatively or in the immediate postoperative period and are largely attributable to progressive right heart failure and hemodynamic collapse.



Severe posttransplant hypoxemia is defined as a saturation of <85%, for ≥1 h despite an FiO2 of 100% with a PEEP of ≥10 mm Hg, and which is out of proportion to any other concurrent lung process
Severe Hypoxemia
These patients should generally be kept dry to avoid pulmonary edema, which can compound hypoxemia related to intrapulmonary shunt
However, oxygen delivery should be maintained with Hgb ≥10 and sufficient cardiac output for a normal SVO2 (low SVO2 has a disproportional effect on SaO2 due to intrapulmonary shunt)
If other causes (e.g., pneumonia) are contributing to hypoxemia, consider alternative ventilatory strategies as appropriate

Proposed management algorithm for severe hypoxemia after liver transplantation in the hepatopulmonary syndrome. Am J Transplant. 2015;15(4):903–913.)*

Several case series document successful transplantation of patients with severe PPH who responded favorably to the preoperative initiation of vasodilator agents.[274–276] For such patients, intravenous or inhaled epoprostenol or similar agent should be employed in the perioperative period. Since pulmonary hypertension tends to persist despite transplantation, these patients frequently require long-term therapy but can often be transitioned to oral vasodilator agents.

Heart Transplantation

Heart transplant recipients are subject to the same generic perioperative pulmonary complications encountered in the general cardiac surgical population. These include atelectasis, pulmonary edema, pleural effusions, and mediastinitis. The mean duration of mechanical ventilation following heart transplantation documented in two published series was 71.8 ± 12.6 h and 42.3 ± 59.5 h, but the need for ventilatory support beyond the initial perioperative period appears to be low.[277,278] In a series of 157 consecutive heart transplant procedures, prolonged respiratory failure requiring tracheostomy was reported in only 7 cases (4.4%), 5 of which occurred within the first 6 months following transplantation.[279]

Kidney Transplantation

Kidney transplantation is carried out with relatively few perioperative pulmonary complications, reflecting the use of a pelvic incision and the comparative good health of the recipients. The vast majority of patients are extubated in the operating room. Perioperative respiratory failure was documented in only 4% of 178 kidney transplant recipients from the University of Pittsburgh.[280] The most common noninfectious pulmonary complication is hydrostatic pulmonary edema due to impaired salt and water excretion in the setting of early allograft dysfunction or rejection. Contemporary studies of renal transplant patients admitted to the ICU with respiratory failure suggest that this is typically a late complication rather than a perioperative one. In a French multicenter study of 6800 kidney transplant recipients, the median time from transplant to ICU admission for respiratory failure was 17 months.[281] Respiratory failure was documented in 10% of a cohort of 540 consecutive adult renal transplant recipients from a center in Turkey, but the median time from transplantation was 10 months.[282] Similarly, ARDS occurs infrequently. In a retrospective review of a national kidney transplant database encompassing over 42,000 transplants, ARDS was documented in only 86 patients (0.2%) and only 1 of these cases occurred within the perioperative period.[283]

■ Pleural Effusions

Development of pleural effusions in the setting of liver, heart, and kidney transplantation is considered below.

Liver Transplantation

Postoperative pleural effusions are present in 40% to 100% of liver transplant recipients.[284–286] Effusions are exudative in up to 43% of cases and are typically right-sided or bilateral but are rarely exclusively on the left.[286] In a minority of patients, they may occupy greater than half of the hemithorax. Disruption of diaphragmatic lymphatics during hepatectomy is postulated to be the principal mechanism of fluid accumulation. Other contributing mechanisms include volume overload, hypoalbuminemia, and preexisting hepatic hydrothorax. Effusions may enlarge over the first postoperative week but typically resolve by the third week. The need for drainage because of perceived respiratory compromise has been reported in up to 31% of patients.[253,284,285] Effusions that continue to enlarge beyond the first week, persist beyond 3 weeks, or involve only the left hemithorax should be sampled to rule out other causes. Persistent or enlarging effusions should also prompt consideration of subdiaphragmatic processes including hematoma, biloma, or subphrenic abscess.

Heart Transplantation

In a series of 72 heart transplant recipients, the prevalence of pleural effusions within the first 12 months following transplantation was 85%.[287] Most of these effusions developed in the early postoperative period and were bilateral in 68%, left-sided in 14%, and right-sided in 3%. The majority of effusions were small; only 13% occupied >25% of the hemithorax. Effusions were largest between postoperative days 5 and 7, and most resolved by the end of the first year. Factors contributing to the development of pleural effusions following heart transplantation include lymphatic disruption, congestive heart failure, and postsurgical hemorrhage. Other uncommon causes that have been reported include malignancy, pericarditis, chylothorax, and idiopathic.

Kidney Transplantation

Pleural effusions in kidney transplant recipients most commonly occur in the setting of volume overload. Obstruction of the transplanted ureter causing urinothorax is a rare cause of pleural effusion; the fluid is transudative, with a pH <7.3 and a pleural fluid–to–serum creatinine ratio >1.

■ Diaphragmatic Disorders

Diaphragmatic disorders in the setting of lung, heart, and kidney transplantation are briefly considered in the sections that follow.

Liver Transplantation

Right-sided diaphragmatic dysfunction following liver transplantation is postulated to result from crush injury to the right phrenic nerve by the suprahepatic vena caval clamp placed during surgery. In one older series of 48 patients, evidence of delayed or absent right-sided phrenic nerve conduction was found in 79% of patients while the left phrenic conducted normally in all cases.[288] In 38% of patients, there was associated right diaphragmatic paralysis documented by ultrasound. Phrenic nerve injury was not associated with increased duration of mechanical ventilatory support or hospital stay. In a subset of patients followed with serial testing, abnormalities in phrenic nerve conduction and diaphragmatic excursion normalized by 9 months after surgery. Newer surgical approaches have been introduced that preserve the suprahepatic inferior vena cava, thereby minimizing the risk of phrenic nerve injury.[289]

Heart Transplantation

Diaphragmatic dysfunction due to phrenic nerve injury occurs in up to 12% of heart transplant recipients.[290] The right phrenic nerve is most prone to injury. Diaphragmatic dysfunction has been associated with an increased risk of postoperative pneumonia and a trend toward increased length of intubation.

Diaphragmatic hernias have been reported in heart transplant recipients who had left ventricular assist devices (LVAD) implanted prior to transplantation. These devices are placed either preperitoneally or intraperitoneally in the left upper quadrant. The inflow cannula penetrates the left hemidiaphragm and attaches to the left ventricle, while the outflow cannula emerges from the ascending aorta and crosses anterior to the diaphragm near the midline. At the time of heart transplantation, the LVAD is explanted and the left sided diaphragmatic defect is routinely repaired. However, repair of the anterior diaphragmatic defect is not necessarily standard practice, as it has been reasoned this would add to the operative time and that midline scarring would naturally close the rent. The incidence of diaphragmatic hernias has been reported to be as high as 16% among heart transplant recipients in whom closure of the anterior midline diaphragmatic defect was not performed, and in all cases the hernia arose at the site of the unrepaired midline defect.[291] In contrast, only 4% to 5% of patients experienced this complication when the surgical procedure was modified to include routine closure of the anterior defect at the time of LVAD explantation.[291,292]

Patients with diaphragmatic hernias can be entirely asymptomatic, experience subacute gastrointestinal symptoms (abdominal pain, nausea, vomiting), or present emergently with colonic incarceration. Chest radiographs can be nonspecific, demonstrating only an ill-defined opacity at the base of the right or left lung. More suggestive findings include the presence of air within the opacity or actual visualization of colonic haustra. The diagnosis can usually be established definitively with CT of the chest and abdomen, after administration of oral contrast. Surgical repair, either via conventional laparotomy or laparoscopically, is indicated even in asymptomatic cases because of risk of incarceration.

■ Neoplastic Disorders

Posttransplant lymphoproliferative disorder (PTLD) is second only to nonmelanoma skin cancers as a leading neoplastic complication of organ transplantation. PTLD encompasses a spectrum of abnormal B cell proliferative responses ranging from benign polyclonal hyperplasia to malignant lymphomas. Epstein-Barr virus (EBV) has been identified as the stimulus for B-cell proliferation, which proceeds in an unchecked fashion due to the inadequate cytotoxic T cell response in the immunosuppressed host. EBV-naïve recipients who acquire primary infection at the time of organ transplantation are at greatest risk of developing PTLD. A higher intensity of immunosuppression and, in particular, use of antilymphocyte antibody preparations have also been implicated as risk factors. Likely reflecting differences in the magnitude of immunosuppression employed, the incidence of PTLD is only 1% to 2% among kidney and liver transplant recipients but is in the range of 5% to 7% among heart transplant recipients.[293,294] The incidence is greatest within the first year posttransplantation. Among the non-lung organ transplant populations, heart transplant recipients are the most likely to present with intrathoracic involvement, which typically assumes the form of one or multiple pulmonary nodules occasionally accompanied by regional adenopathy or pleural effusions.

Initial treatment involves reduction in the level of immunosuppression to permit partial restoration of host cellular immunity. Such a strategy can lead to regression of tumor in up to two-thirds of solid organ recipients but carries the risk of precipitating acute or chronic allograft rejection.[295] For patients who fail to achieve a complete remission, cannot tolerate reduced immunosuppression, or have widespread disease, immunotherapy with anti-CD20 monoclonal antibodies (rituximab) is the preferred option. Experience with standard chemotherapy has been poor due to the high risk of infection during periods of neutropenia.

The mortality rate attributable to PTLD is not well defined. In multivariate analysis, increased age, elevated lactate dehydrogenase levels, severe organ dysfunction, presence of B symptoms, and multiorgan involvement are independent markers of poor prognosis.[295]

Other malignancies occasionally present in the lungs following transplantation. Bronchogenic carcinoma develops in 2% to 4% of heart transplant recipients.[296] It is unclear whether the development of lung cancer in the heart transplant population reflects an increased risk or simply represents the expected occurrence rate in a population with a high prevalence of cigarette smoking. Among liver transplant recipients with a pretransplantation history of hepatocellular carcinoma, the lung is the most common site of recurrence. Recurrence usually occurs within 2 years of transplantation and appears radiographically as single or multiple lung nodules. An elevated α-fetoprotein level provides an important clue to the possibility of recurrent disease.

Drug-Induced Lung Disease

Sirolimus, also known as rapamycin, is a potent immunosuppressive agent recently introduced into clinical practice. Since its release, numerous cases of interstitial pneumonitis developing in association with sirolimus administration have been reported.[297,298] The incidence of this complication remains unknown. Initial reports suggested that interstitial pneumonitis was largely a result of excessive sirolimus blood concentrations, but subsequent reports described this complication in the setting of therapeutic drug levels.[298,299]

Patients typically present with dry cough, progressive dyspnea, fatigue, and weakness; fever and hemoptysis are less commonly present. Radiographic abnormalities include interstitial infiltrates, alveolar consolidation, and nodular opacities. Bronchoalveolar lavage reveals evidence of a lymphocytic alveolitis and, less commonly, of alveolar hemorrhage. Reported findings on transbronchial lung biopsies include bronchiolitis obliterans with organizing pneumonia, interstitial lymphocytic infiltrates, and nonnecrotizing granulomas. Discontinuation of the drug may be sufficient treatment in many cases; corticosteroids have been given to hasten resolution, but support for this approach is anecdotal. Conversion from sirolimus to everolimus, an agent that shares similar biochemical features and mechanism of action, has led to resolution of pneumonitis in some cases.[300,301] However, interstitial pneumonitis and diffuse alveolar hemorrhage also have been reported in solid organ transplant recipients receiving everolimus.[302,303] In one study of 409 renal transplant recipients receiving an mTOR inhibitor as part of maintenance immunosuppression, the incidence of pneumonitis was 4.8% among those receiving sirolimus and 6.8% among those receiving everolimus, suggesting that pulmonary toxicity is likely to be a class effect.[304]

The interleukin 2 receptor antagonist basiliximab is commonly used as an induction agent, in part because of a generally favorable side effect profile. However, several cases of noncardiogenic pulmonary edema in renal transplant recipients have been reported in association with basiliximab infusion.[305]

Pulmonary Metastatic Calcification

Deposition of calcium in the lung parenchyma and other organs is a well-documented complication of chronic renal failure and is postulated to relate to alterations in calcium and phosphate balance and parathyroid hormone secretion.[306] Although renal transplantation should have a mitigating effect, pulmonary metastatic calcification rarely may progress despite successful transplantation[307,308] and may accelerate in association with graft failure.[309,310] Pulmonary metastatic calcification has also been described in liver transplant recipients, with a reported incidence in two series of 5.2% and 47%.[311,312] Renal insufficiency was a common but not universal feature in these patients. Secondary hyperparathyroidism, due to transient hypocalcemia induced by large volume infusion of citrate-containing blood products and, when present, to renal insufficiency, has been offered as a possible mechanism.[312]

Metastatic pulmonary calcification is most often clinically silent but rarely may lead to restrictive lung disease or fulminant respiratory failure.[309,310,313] The major import of this disorder lies in its ability to radiographically mimic more ominous processes such as infection or malignancy. Single or multiple nodular opacities or areas of alveolar consolidation are seen on plain chest radiographs, but calcification of these lesions may not be apparent. CT findings include multiple diffuse calcified nodules, diffuse or patchy areas of ground-glass opacity or consolidation, and confluent high-attenuation parenchymal consolidation. The abnormalities are typically most pronounced in the upper lung zones. Calcification is evident by CT in approximately 60% of cases. In the absence of calcification, the demonstration of high-attenuation (>100 HU) parenchymal opacities by CT scan or of increased uptake of tracer in the lung by technetium bone scintigraphy is helpful in establishing a diagnosis. In instances of diagnostic uncertainty, transbronchial or surgical lung biopsy may be necessary. There is no established treatment for pulmonary metastatic calcification but, given the overall favorable prognosis, this is rarely a consideration.

CHAPTER 95

Pulmonary Complications of Sickle Cell Disease

Roberto F. Machado
Mark T. Gladwin

INTRODUCTION

Sickle cell disease (SCD) is one of the most common monogenetic diseases in the world.[1] Sickle cell anemia, the most common and most severe form of SCD, occurs in individuals who are homozygous for a single GAG to GTG substitution in the β-globin gene, resulting in the production of hemoglobin S (HbS). Patients with other types of SCD are compound heterozygotes, having one copy of HbS and one copy of another β-globin mutation, such as hemoglobin SC or HbS-β thalassemia.[2] The presence of concurrent α-thalassemia, which will reduce the intracellular concentration of hemoglobin, also modulates disease severity and accounts for some of the variability in the clinical presentation of patients with SCD.[3] It is estimated that approximately 250,000 children worldwide are born with homozygous sickle cell (HbSS) anemia every year.[4] Approximately 0.15% of African Americans are homozygous for SCD, and 8% have sickle cell trait. In sub-Saharan Africa, up to 40% of the population carry sickle cell trait, and up to 1% of children are born with SCD.[5]

Despite significant improvements in the life expectancy of patients with SCD, estimates of the median age at death range from 42 to 53 years for men and 48 to 58.5 years for women.[3,6–8] Within this context, pulmonary complications of SCD are common and a major threat to the well-being of patients with SCD, accounting for a large proportion of deaths among these patients.[7,9–11] According to the Cooperative Study of Sickle Cell Disease (CSSCD), a prospective multicenter study of 3764 patients, more than 20% of adults likely had fatal pulmonary complications of SCD.[7] Among the 299 patients enrolled in the long-term follow-up study of those who participated in the Multicenter Study of Hydroxyurea in Sickle Cell Anemia (MSH), pulmonary disease was the most common cause of mortality, accounting for 28% of all deaths.[12] The numbers likely underestimate the importance of pulmonary disease in risk of death, as pulmonary hypertension (PH) was not diagnosed in these cohorts. Indeed, retrospective evaluation of banked plasma samples from the studies using N-terminal pro–brain natriuretic peptide (NT-proBNP) as a surrogate for the presence of PH suggested that PH was a major risk factor for death in both the CSSCD and MSH cohorts.[13,14]

When deoxygenated, HbS is much less soluble than normal hemoglobin (HbA).[15,16] Deoxygenated HbS polymerizes and aggregates inside sickle erythrocytes as they traverse the microcirculation. Rigid, dense, and sickled cells can become physically entrapped in the microcirculation, a process that is enhanced by inflammation and integrin molecule expression, causing red cell and leukocyte adhesion to endothelium. Mechanistic studies in transgenic mice expressing exclusively human HbS suggests that microvascular occlusion results in episodic interruption in blood flow, ischemia, and reperfusion injury, with secondary inflammatory, thrombotic, and oxidant stress.[17–24]

In patients, vaso-occlusion leads to the frequent episodes of bone pain and acute chest syndrome (ACS) that complicate SCD. Furthermore, the membrane of erythrocytes containing intracellular HbS polymer is constantly exposed to mechanical and oxidant injury as the red cells traverse the microcirculation. Ultimately, cumulative membrane damage shortens red cell life span, so that SCD is characterized by a chronic hemolytic anemia. Intravascular hemolysis releases cell-free hemoglobin into the plasma, which scavenges nitric oxide (NO) and releases red blood cell arginase 1 into the plasma, which, in turn, catabolizes arginine, the substrate for NO synthesis.[25–27] Hemolysis can also promote inflammasome-mediated sterile inflammation and endothelial cell death.[28–34] Hence, intravascular hemolysis produces a state of endothelial dysfunction and vascular proliferation, along with prooxidant and proinflammatory stress.[35–37] In effect, intraerythrocytic HbS polymerization leads to downstream vascular inflammation, hemolysis-related vasculopathy, and ischemia–reperfusion organ injury.

Anemia, per se, should also be considered in the evaluation of the cardiopulmonary effects of SCD, since decreasing oxygen carrying capacity of the blood related to severe anemia can impair cardiopulmonary function. The signs and symptoms induced by anemia depend on the degree of anemia, the rate at which it evolves, the oxygen demands of the patient, and the presence of chronic cardiopulmonary disease. For instance, in resting adults subjected to acute isovolemic anemia, oxygen delivery can be maintained at hemoglobin concentrations as low as 5 g/dL,[38] a finding also noted in individuals with chronic severe anemia.[39,40] Thus, anemia, even when severe, rarely causes heart failure; when it does, it is likely that the high-output failure is superimposed upon an underlying cardiac abnormality.

From the hemodynamic standpoint, as hemoglobin level decreases (particularly with hemoglobin values <7 g/dL), blood viscosity decreases, cardiac output increases, cardiac filling pressures tend to decrease, and systemic and pulmonary vascular resistances decrease substantially. As such, because of anemia, the pulmonary vascular resistance in patients with sickle cell disease without pulmonary hypertension ranges from 68 to 74 dyn • sec • cm^{-5}, as compared with the measured values in non-anemic healthy volunteers of 80 to 120 dyn • sec • cm^{-5} (or about 1 Wood Unit).[41] Anemia also lowers blood viscosity and may lead to an underestimation of the severity of pulmonary vascular disease.[42] Combined, these abnormalities may lead to an underestimation of the severity of pulmonary vascular disease in patients with SCD. Such abnormalities are readily reversible with red blood cell transfusions.[39,40,43] Finally, in severe cases, especially in patients with cardiopulmonary disease, anemic hypoxia can also occur as a consequence of reduced ability of blood to participate in gas exchange and oxygen transport. Interestingly, the severity of hemolytic anemia in patients with SCD is strongly correlated with systemic hypoxemia and decreasing arterial hemoglobin oxygen saturation, a finding that is likely related to both increased cardiac output and altered pulmonary vascular perfusion. Alterations in pulmonary vascular perfusion result in impaired ventilation–perfusion matching.[44,45]

ACUTE CHEST SYNDROME

The ACS in SCD is defined as a lung injury syndrome characterized by a new pulmonary infiltrate that (1) is consistent with alveolar consolidation, rather than atelectasis; (2) involves at least one complete lung segment; and (3) is accompanied by chest pain, fever, tachypnea, wheezing, or cough.[46]

■ Epidemiology

ACS is the second most common cause of hospitalization in patients with SCD, the leading cause of admission to an intensive care unit, and, together with PH, a leading cause of premature death, accounting for 25% of SCD-related mortality in earlier cohorts.[7,10] More recently, increased awareness, the chronic use of hydroxyurea, and the early and aggressive use of transfusion therapy have led to a decrease in ACS-related mortality.[47] For example, in a multicenter trial of inhaled NO for vaso-occlusive crisis, only 10% of patients in the study developed ACS, and none required mechanical ventilation or died.[47]

ACS can occur in any of the sickle hemoglobinopathies, but it is more common in individuals with HbSS disease. In the CSSCD, a 29% incidence of the ACS was noted in 3751 subjects over a 2-year period, representing an attack rate of 12.8 episodes per 100 patient-years for homozygous HbS disease.[7] The incidence is higher in children than in adults (24.5 vs. 8.8 events per 100 patient-years). As many as half of episodes of ACS occur in association with vaso-occlusive pain crises, and a significant proportion of patients will have a painful event within 2 weeks of the diagnosis of ACS.[48,49] Some 10% to 20% of patients admitted with an acute vaso-occlusive pain crisis develop ACS within the first 3 days of hospitalization. Recent studies suggest a much higher rate of ACS following influenza infection.[50–52]

Clinical parameters that appear to increase risk for, or are associated with, development of ACS include young age, active smoking, environmental smoke exposure,[53] major surgical procedures, acute rib infarcts, avascular necrosis of the hips, pregnancy, use of narcotics, acute anemic events, nocturnal or daytime hypoxemia, and previous pulmonary events.[48,49] In children, a number of studies suggest that asthma is a risk factor for the development of ACS.[54–56] Laboratory parameters in steady state associated with an increased risk for the development of ACS include an elevated white blood cell count, higher steady-state level of hemoglobin, and lower steady-state level of fetal hemoglobin.[48,49]

While a high steady-state level of hemoglobin is a risk factor for ACS, during acute hospitalization for a vaso-occlusive crisis, development of the ACS is often preceded by an abrupt drop in hemoglobin (mean decrease of 0.78 g/dL) and increases in markers of hemolysis—for example, lactate dehydrogenase. The platelet count also may fall prior to ACS, and platelet levels lower than 200,000 cells per mL constitute an independent risk factor for the severity of ACS, an increased risk of neurologic complications, and the need for mechanical ventilation.

A limited number of studies have addressed the role of candidate gene polymorphisms in patients with ACS. In a small cohort of 134 pediatric patients with SCD, *NOS1* AAT repeat polymorphism in intron 13 was associated with increased risk of ACS.[57] Similarly, in a study of 173 pediatric patients with SCD, individuals homozygous for an *ET-1* T8002 C polymorphism had higher rates of ACS, while those homozygous for a *NOS3* T-786 C polymorphism had lower rates.[58] Finally, in a cohort of 942 children with SCD, a highly polymorphic (GT)n dinucleotide repeat located in the promoter region of *HMOX1*, with long repeat lengths linked to decreased activity and inducibility, was evaluated. After adjusting for sex, age, asthma, percentage of fetal hemoglobin, and α-globin gene deletion, children with two shorter alleles had lower rates of hospitalization for ACS compared with children with longer allele lengths.[59]

■ Pathogenesis

The etiology of ACS is multifactorial. Although a specific cause is not identified in a substantial proportion of patients, three major pathogenetic mechanisms are involved, including infection, bone marrow fat embolization, and direct red cell intravascular sequestration, which cause lung injury and infarction (Table 95-1, Fig. 95-1).

TABLE 95-1 Causes of the Acute Chest Syndrome[a]

Cause	All Episodes (*n* = 670)	Age at Episode of Acute Chest Syndrome		
		No. of Episodes (%)		
		0–9 y (*n* = 329)	10–19 y (*n* = 188)	≥20 y (*n* = 153)
Fat embolism, with or without infection[b]	59 (8.8)	24	16	19
Chlamydia[c]	48 (7.2)	19	15	14
Mycoplasma[d]	44 (6.6)	29	7	8
Virus	43 (6.4)	36	5	2
Bacteria	30 (4.5)	13	15	12
Mixed infections	25 (3.7)	16	6	3
Legionella	4 (0.6)	3	0	1
Miscellaneous infections[e]	3 (0.4)	0	3	0
Infarction[f]	108 (16.1)	50	43	15
Unknown[g]	306 (45.7)	139	88	79

[a] *Data on one episode were excluded because the patient's birth date was not known.*

[b] *Nineteen of the episodes of pulmonary fat embolism were associated with infectious pathogens.*

[c] *This category included episodes in which Chlamydia alone was identified, but not episodes involving mixed infections or pulmonary fat embolism.*

[d] *This category included only episodes in which only Mycoplasma pneumoniae or Mycoplasma hominis was identified, but not episodes involving mixed infections, Mycobacterium tuberculosis, or pulmonary fat embolism.*

[e] *This category included two cases of tuberculosis and one case of Mycobacterium avium complex infection.*

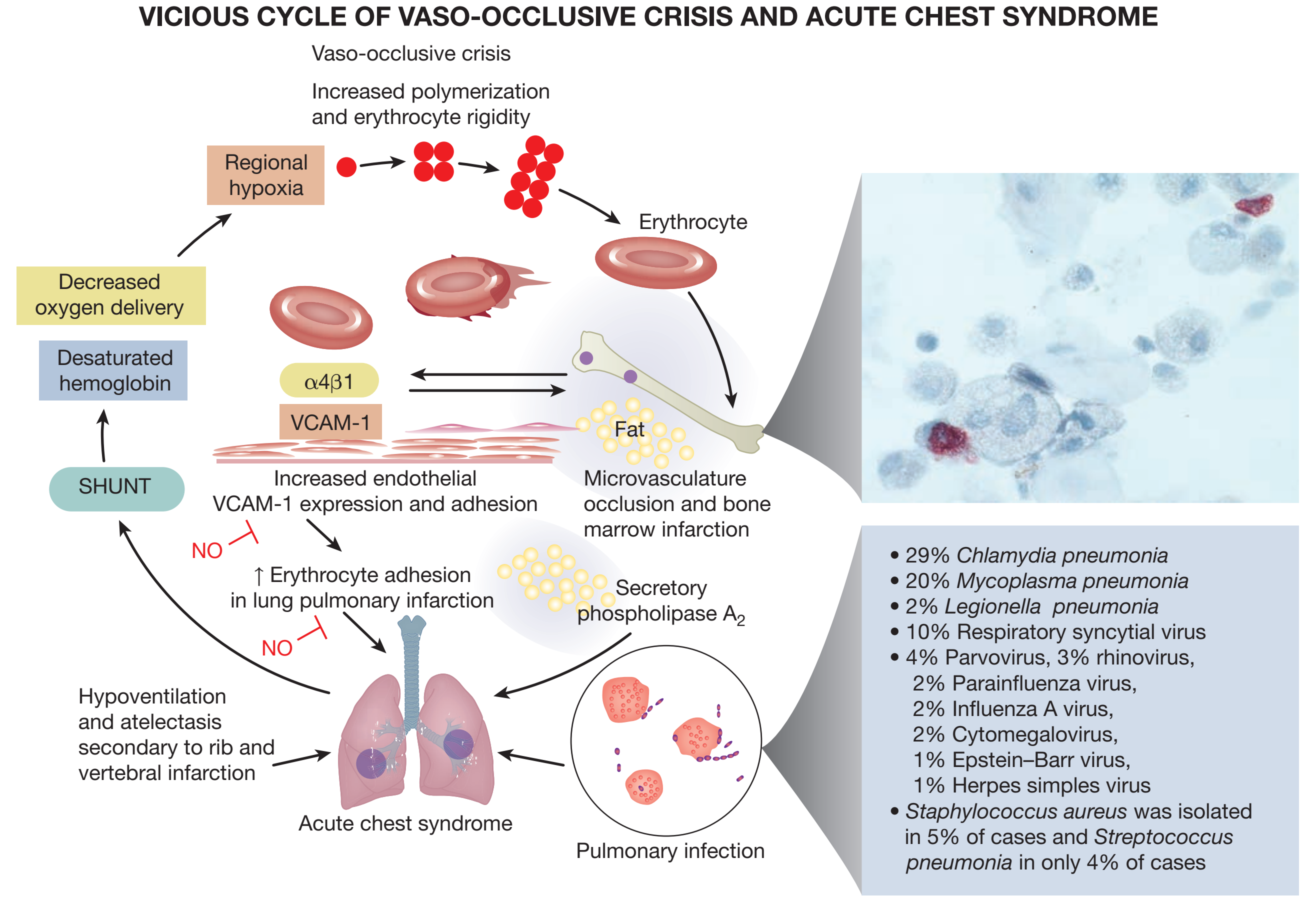
[f] *A pulmonary infarction was presumed to have occurred when the results of the analysis for pulmonary fat embolism, bacterial studies, viral isolation studies, and serologic tests were complete and were all negative.*

[g] *The cause of episodes for which some or all of the diagnostic data were incomplete and no etiologic agent was identified was considered to be unknown.*

Reproduced with permission from Vichinsky EP, Neumayr LD, Earles AN, et al. Causes and outcomes of the acute chest syndrome in sickle cell disease. National Acute Chest Syndrome Study Group. N Engl J Med. 2000;342(25):1855–1865.

The most common etiology of ACS in both children and adults is infection by a community-acquired pathogen. It has been proposed that community-acquired respiratory infection induces an excessive inflammatory lung injury response in patients with SCD, as SCD mice that express only human HbS show increased susceptibility to inflammatory triggers (lipopolysaccharide and bacteria) and development of lung injury at lower levels of endotoxin that do not adversely affect wild-type mice.[60,61] In addition, more than 80% of adults with SCD report a history of having been admitted to the hospital for "pneumonia."[35]

The National ACS Study Group analyzed 671 episodes of ACS in 538 patients with SCD. Respiratory samples obtained from sputum and BAL were analyzed for viral and bacterial infections.[46] Among the infectious agents identified most commonly (Table 95-1) were atypical bacteria and viruses, including *Chlamydia pneumonia* (29%), *Mycoplasma pneumonia* (20%), *Legionella pneumophila* (2%), respiratory syncytial virus (10%), parvovirus (4%), rhinovirus (3%), parainfluenza virus (2%), influenza A virus (2%), cytomegalovirus (2%), Epstein–Barr virus (1%), and herpes simplex virus (1%). Community-acquired encapsulated bacteria were rarely isolated, despite the fact that patients with homozygous HbS disease rarely have normal splenic function. *Staphylococcus aureus* was isolated in 5% of cases and *Streptococcus pneumoniae* in only 4% of cases.



VICIOUS CYCLE OF VASO-OCCLUSIVE CRISIS AND ACUTE CHEST SYNDROME
Vaso-occlusive crisis
Increased polymerization and erythrocyte rigidity
Regional hypoxia
Erythrocyte
Decreased oxygen delivery
Desaturated hemoglobin
α4β1
VCAM-1
Fat
SHUNT
Increased endothelial VCAM-1 expression and adhesion
Microvasculature occlusion and bone marrow infarction
NO
↑ Erythrocyte adhesion in lung pulmonary infarction
Secretory phospholipase A2
NO
Hypoventilation and atelectasis secondary to rib and vertebral infarction
Acute chest syndrome
Pulmonary infection
• 29% Chlamydia pneumonia
• 20% Mycoplasma pneumonia
• 2% Legionella pneumonia
• 10% Respiratory syncytial virus
• 4% Parvovirus, 3% rhinovirus, 2% Parainfluenza virus, 2% Influenza A virus, 2% Cytomegalovirus, 1% Epstein–Barr virus, 1% Herpes simples virus
• Staphylococcus aureus was isolated in 5% of cases and Streptococcus pneumonia in only 4% of cases

Figure 95-1 Pathogenesis of the acute chest syndrome. Three major mechanisms are associated with the development of ACS: infection, bone marrow fat embolization, and direct red cell intravascular sequestration causing lung injury and infarction. Lung injury results in ventilation–perfusion mismatch and hypoxemia, which leads to increased hemoglobin S polymerization and erythrocyte vaso-occlusion. This worsens bone marrow infarction and pulmonary vaso-occlusion to promote a vicious cycle. Fat embolization can be diagnosed by Oil Red O staining of pulmonary alveolar macrophages, revealing the characteristic red lipid inclusions. Common infectious organisms identified in cases of ACS are listed. *(Reproduced with permission from Gladwin MT, Vichinsky E. Pulmonary complications of sickle cell disease. N Engl J Med. 2008;359(21):2254–2265.)*

Cases of severe ACS related to seasonal influenza also have been described.[50–52]

Fat embolization syndrome occurs as a complication of vaso-occlusive pain crisis involving multiple bones, resulting in bone marrow edema, infarction, and necrosis. Fat embolism was identified by the National ACS Study Group as the cause of ACS in 16% of patients. During fat embolization, bone marrow contents are released into the systemic circulation and are trapped in the pulmonary circulation, producing acute PH, severe lung inflammation, and hypoxemia (Fig. 95-2).[62–64] Bone marrow fat released into the bloodstream is also converted to free fatty acids by secretory phospholipase A_2, producing direct inflammatory lung injury.[65]

In approximately 20% of patients, direct adhesion of sickled cells in the pulmonary vasculature arising during lung infarction or lung vaso-occlusion is associated with the development of ACS; a small fraction of patients develop wedge-shaped infarctions, sometimes followed by central cavitation.[66] In situ pulmonary arterial thrombosis and cellular occlusion also appear to be common in patients with ACS. In a study of 144 episodes of ACS in 125 consecutive patients evaluated using CT angiography, a 17% prevalence of subsegmental thromboembolism was noted; there was no evidence of peripheral venous thrombosis.[67]

A potential role for hemolysis-derived plasma-free hemoglobin and its by-products, such as free heme, has been suggested in the pathogenesis of ACS. In children with SCD, multivariable regression analysis identified that higher plasma free heme was associated with increased odds of vaso-occlusive crisis and ACS.[68] Administration of lysed red blood cells into the circulation of sickle cell mice has been shown to increase vascular permeability in the lung without impacting permeability in other organs.[69] Furthermore, studies have demonstrated that intravenous administration of heme to sickle cell mice induces severe and lethal acute lung injury.[70] In aggregate, these data suggest that plasma-free hemoglobin or heme specifically may directly contribute to lung injury in the context of vaso-occlusive crisis and ACS. The relationship between increased intravascular hemolysis and thrombocytopenia (see below) suggests that a possible thrombotic thrombocytopenic purpura–like mechanism may occur in a subset of patients with ACS. In fact, studies have demonstrated that hemoglobin produced during hemolysis may inhibit ADAMTS13 activity.[71–73]

■ Clinical Features and Evaluation

About 80% of patients with ACS present with fever and 62% with cough; approximately 40% have chest pain, tachypnea, dyspnea, and abdominal, arm, leg, rib, or sternal pain.[46] Some of the clinical features of ACS are age dependent, which likely reflects the different disease etiologies in different age groups. Children have a higher proportion of infectious etiologies in comparison to adults, who have fat embolization as a major cause. Most adult patients present with severe extremity or chest pain and develop ACS 24 to 72 h later.

Pulmonary complications of hemoglobinopathies. Chest. 2010;138(4):973–983.)*

Reactive airway disease is observed in 13% of cases and is much more common in children.[46]

ACS is associated with signs of systemic inflammation. Mean peak temperature is 38.9°C and mean white blood cell count is 23,000 cells per mL. In addition, a drop in hemoglobin level (mean decrease of 0.78 g/dL from steady-state level) and an increase in markers of hemolysis are noted.[46] Thrombocytopenia also may occur; platelet counts less than 200,000 cells per mL appear to be a marker of more severe ACS and are associated with increased risk of neurologic complications and need for mechanical ventilation.[46] Secretory phospholipase A_2 levels, which are elevated early in the course of ACS even before development of radiographic changes, have been used to predict onset of the syndrome.[74]

Some patients manifest evidence of systemic fat embolization. In these cases, ACS is part of the spectrum of the systemic fat emboli syndrome, evident as acute multiorgan system failure (MOSF) (Chapter 142). Patients with MOSF experience acute hypoxic respiratory failure, acute cor pulmonale, renal and hepatic dysfunction, alterations in mental status, seizures, thrombocytopenia, and coagulopathy.[75,76]

The diagnosis of pulmonary fat embolization syndrome is based on identification of Oil Red O–positive lipid accumulations within alveolar macrophages, as the clinical manifestations can be indistinguishable from other causes of ACS (Fig. 95-2). Bronchoscopy has been used as the diagnostic modality of choice for the diagnosis of pulmonary fat embolization syndrome. Interestingly, a study comparing the diagnostic utility of induced sputum sampling of alveolar macrophages with specimens obtained from bronchoalveolar lavage found a significant, albeit modest, correlation between the two ($r = 0.65$).[77] Patients with ACS who have lipid-laden macrophages detected in induced sputum have significantly more extrathoracic pain than those without evidence of fat emboli, more neurologic symptoms, a lower platelet count, and higher serum transaminase levels.[77]

The mean length of hospitalization for ACS is 10.5 days, compared with 3 to 4 days for uncomplicated vaso-occlusive painful crisis. Large registry studies suggest that 13% of patients require mechanical ventilation. The overall mortality is 3% for all patients and 9% for adults; however, as noted previously, these rates may be lower in experienced medical centers employing more aggressive and earlier transfusion therapy.

Risk factors for mechanical ventilation and poor outcome include a platelet count less than 200,000 per µL (likely indicative of the fat emboli syndrome), a greater number of lobes involved on the chest radiograph, and a self-reported or medical record–based history of cardiac disease.

Acute cor pulmonale also can complicate the course of ACS. In a study of 84 consecutive patients hospitalized with ACS, 13% manifested right heart failure. This subgroup had significant elevations in B-type natriuretic peptide and troponin I levels and the highest risk for needing mechanical ventilation and death.[78] PH and right heart dysfunction appear to represent major comorbidities in ACS; right heart failure should be considered in those patients presenting with shock or severe hypoxia.

■ Treatment

Since the triggers and risk factors for ACS are well known, preventive strategies in the outpatient setting, clinical surveillance, and aggressive and early therapy are likely to improve prognosis.

Patients with multiple episodes of vaso-occlusive crises or a previous history of ACS should be treated with hydroxyurea in the outpatient setting, since its use has been shown to reduce the risk of developing ACS by approximately 50%.[79,80] A chronic transfusion regimen also is effective in reducing the incidence of ACS,[81] as is preoperative blood transfusion in patients undergoing surgical procedures.[82] L-glutamine,[83] voxelotor,[84] and crizanlizumab[85] have demonstrated potential efficacy in decreasing the incidence of vaso-occlusive painful events, but a direct effect on the incidence of ACS has not been studied; thus, there is insufficient evidence to determine their efficacy for the prevention of ACS.

In acutely ill patients, specific strategies, such as aggressive pain management and incentive spirometry, can minimize chest wall splinting, mitigating development of atelectasis and alveolar hypoxia. The use of incentive spirometry has been shown to decrease the incidence of new pulmonary infiltrates in patients admitted with vaso-occlusive pain affecting the chest wall.[66]

In one small study evaluating the efficacy of prophylactic blood transfusions in patients with serum phospholipase A_2 elevations during vaso-occlusive crisis,[86] transfusion eliminated ACS in the study cohort. Larger confirmatory trials are indicated.

We recommend use of empiric antimicrobial therapy in all patients with ACS, given the high prevalence of infectious etiologies. Coverage should include agents effective against atypical bacteria and encapsulated organisms. Important to consider are alternative organisms, such as methicillin-resistant *Staphylococcus aureus* (MRSA) and influenza viruses, especially in patients who do not respond to therapy or who develop ACS during influenza season. A recent observational cohort study suggests that a procalcitonin-guided strategy to prescribe antibiotics in patients with ACS may reduce antibiotic exposure with no apparent adverse outcomes.[87]

Although not demonstrated in randomized trials, blood transfusion remains the mainstay of ACS therapy and is considered standard of care. Acute red cell transfusion increases PaO_2 and hemoglobin oxygen saturation and may rapidly resolve the pulmonary event.[46,88] In the DeNOVO trial,[47] no episodes of ventilator-dependent respiratory failure and no deaths were noted in 30 patients with ACS receiving the current practice of early transfusion therapy. The improved outcomes compare favorably with historic data from the National ACS Study Group.

To avoid the adverse effects of increased blood viscosity and the consequent risk of vaso-occlusion, the hemoglobin level should not be raised higher than 11 g/dL with simple transfusion therapy. The National Acute Chest Syndrome Study Group found no significant differences in outcomes between patients treated with simple transfusion or red cell exchange (erythrocytapheresis), suggesting that the former approach is preferred as initial therapy.[46] Patients with high initial hemoglobin concentrations (≥9 g/dL) or those with severe or rapidly progressive disease should receive erythrocytapheresis. Most importantly, to decrease the risk of delayed hemolytic transfusion reactions related to alloimmunization against minor red blood cell antigens, all transfused blood should be matched to Rh, C, E, and Kell antigens.

Treatment with corticosteroids has been shown to reduce the severity of pain and length of hospitalization, but this therapy is complicated by a high rate of rebound pain and readmission.[89,90] An investigation of the use of a slow, tapering protocol of corticosteroids to maintain their beneficial effects while limiting rebound pain and readmission was terminated early because of slow accrual of study patients.[91]

Noninvasive mechanical ventilation (NIMV) has been studied in the setting of ACS. In a prospective, randomized, open, single-center study of 67 adult patients with ACS, use of NIMV improved respiratory rate and gas exchange but failed to significantly reduce the number of patients remaining hypoxemic by day 3 of hospitalization; in addition, use of NIMV was associated with greater patient discomfort.[92] In addition, NIMV did not change transfusion rates, pain scores, narcotic dose, or hospital length of stay. In fact, its use prolonged length of stay in the step-down unit.[92]

The DeNOVO trial explored use of inhaled NO for patients with SCD presenting in vaso-occlusive crisis. Despite two prior positive small phase 2 trials,[93,94] the DeNOVO study did not demonstrate an effect of inhaled NO therapy compared with placebo on the duration of pain crisis, narcotic use, pain scores, or development of ACS.[47]

ASTHMA AND AIRWAY REACTIVITY

Asthma is common among patients with SCD, particularly in children. In a prospective study of 291 African-American children with SCD, 17% received a clinical diagnosis of asthma.[54] Interestingly, the reported incidence of airway hyperresponsiveness in children with SCD is much higher, ranging from 40% to 77%, as measured by methacholine, exercise, or cold air challenge tests.[95–97] There is an association between elevated immunoglobulin E levels and asthma or airway hyperresponsiveness in individuals with SCD; this association supports the notion that asthma can be a separate comorbid condition in these patients.[98–100] It is important to point out, however, that data suggest that wheezing and obstructive lung disease may occur independent of a traditional diagnosis of asthma and are a marker of disease severity or an increased capillary blood volume associated with a high output state.[101,102]

Asthma has been associated with multiple complications of SCD, including ACS. Children with SCD and asthma experience almost twice as many episodes of ACS as their counterparts without asthma, even after matching for age, sex, fetal hemoglobin percentage, and lifetime average hematocrit.[54–56,103–106] Several mechanisms have been proposed for this association, including ventilation–perfusion mismatch leading to hypoxemia and sickling, and inflammation causing increased erythrocyte adhesion to vascular endothelium.[107] Asthma is an independent risk factor for mortality in children with SCD, conferring a twofold higher risk of death (hazard ratio [HR], 2.36; confidence interval [CI], 1.21–4.62; $p = 0.01$).[108] The reasons for increased mortality remain unclear but are likely related to the higher risk of vaso-occlusive crises and ACS.

Data on asthma in adults with SCD are scarce. The diagnostic and prognostic significance of the disease in adults is less clear than in children. A study of 31 adults with SCD without a clinical diagnosis of asthma showed an average TLC of 73% predicted, FVC of 79% predicted, and FEV_1 of 75% predicted.[106] Fifteen patients demonstrated bronchial hyperreactivity on methacholine provocation testing; there was evidence of a correlation between bronchial hyperreactivity and previous episodes of ACS. Another cohort study evaluated physician-diagnosed asthma and a history of wheezing in 114 adults with SCD.[109] Although self-reported severe and recurrent wheezing was associated with increased rates of pain, ACS, and risk of death, no relationship was found between a physician-established diagnosis of asthma and these complications.[110]

Although there are no controlled trials of asthma therapy in the SCD population, most experts recommend treatment following generally established guidelines for asthmatics in general.[111] Systemic corticosteroids must be used with caution, however, as corticosteroids appear to induce vaso-occlusive crises and ACS in patients with SCD. In fact, the use of corticosteroids in pediatric patients with SCD has been shown to worsen outcomes.

PULMONARY HYPERTENSION

Among the chronic cardiopulmonary complications of SCD, PH, is the major threat to the well-being and longevity of patients. A number of studies have added significantly to our understanding of the prevalence, underlying pathogenetic mechanisms, and clinical phenotype of patients with PH and SCD. Several screening cohort studies have focused on the prevalence, risk factors, and mortality rate of patients with SCD and PH diagnosed by right heart catheterization. Interestingly, recent studies in patients with many diseases suggest that even borderline values between 20 and 24 mm Hg also increase risk of death and exercise intolerance.[112,113] As a result, the 6th World Symposium in Pulmonary Hypertension has proposed to define all forms of precapillary PH as a mPAP >20 mm Hg and a pulmonary vascular resistance ≥3 Wood Units (240 dyn • s/cm^5).[114] This new definition would potentially lead to reclassification of a substantial number of patients with sickle cell disease as having PH.

■ Epidemiology

Retrospective studies using Doppler echocardiography have demonstrated that 20% to 30% of patients with SCD have an elevated estimated pulmonary artery systolic pressure (PASP) that is two standard deviations above the normal mean value (tricuspid regurgitant jet velocity [TRV] ≥2.5 m/s). Approximately 8% to 10%

have values three standard deviations above the normal mean (≥3.0 m/s).[76,115] These findings have been corroborated in several prospective studies.

In one study using echocardiographic screening, 23% of patients with SCD had borderline or mild elevations in PASP (defined by a TRV ≥2.5–2.9 m/s and corresponding to a PASP of approximately 30–39 mm Hg), and 9% had moderately to severely elevated pressures (defined by TRV ≥3.0 m/s, corresponding to a PASP of approximately 40–45 mm Hg).[35] Similar rates were found in other studies.[116–119]

In a study of patients enrolled in the MSH, plasma NT-proBNP, a prohormone released by right and left ventricular myocardium under pressure stress, was elevated in 30%, suggesting the presence of elevated pulmonary pressures and right heart strain.[13] Similarly, measurements of NT-proBNP in banked plasma from patients enrolled in the CSSCD from 1978 to 1988 revealed that 27.6% of adults had elevated levels.[14] In both studies, elevated study entry levels of NT-proBNP were independently associated with a higher risk of death in prospective follow-up.

Epidemiologic risk factors associated with an elevated TRV include a history of renal or cardiovascular complications, increased systemic systolic blood pressure, abnormalities in markers of hemolytic anemia (anemia; reticulocytosis; and increased lactate dehydrogenase, aspartate aminotransferase, and bilirubin levels), iron overload, cholestatic liver dysfunction (elevations in alkaline phosphatase), renal insufficiency, a history of cutaneous leg ulceration, and, in men, a history of priapism.[13,35] These risk factors have also been observed in studies using right heart catheterization to diagnose PH.[118,120,121] Surprisingly, in these studies development of an elevated TRV was not associated with the number of vaso-occlusive episodes, markers of inflammation, fetal hemoglobin levels, or platelet counts.[13,35] PH determined by right heart catheterization has also been shown not to correlate with episodes of vaso-occlusive crisis or ACS, suggesting that this complication arises secondary to hemolytic anemia, rather than recurrent episodes of vaso-occlusion. A large screening study of 483 patients with homozygous SS disease conducted in the United States and England reproduced these associations;[122] patients with elevations in Doppler-estimated PASP had more severe hemolytic anemia and renal insufficiency. These patients also had lower arterial oxygen saturation, higher levels of NT-proBNP, and lower 6-min walk distances. A high Doppler-estimated pulmonary artery pressure was also independent of rates of vaso-occlusive disease or ACS, providing further support to the hypothesis that this complication arises secondary to chronic hemolytic anemia and end-organ dysfunction (renal and liver disease), rather than episodes of ACS and related pulmonary fibrosis.

An elevated estimated PASP by Doppler-echocardiographic screening or right heart catheterization is a significant risk factor for death in patients with SCD. The risk appears to be linearly related to the elevation in PASP.[35] In one study, a 14% mortality rate over 2 years was reported in patients with an elevated TRV versus a 3% mortality rate in those with normal TRV.[117] Similarly, in another study, the mortality rate over 2.5 years was 25% in patients with an elevated TRV and less than 2% in those with a normal TRV.[116] Consistent with these data, in a cohort of 632 patients with SCD from the United States and England, 11.2% had TRV ≥3.0 m/s and 24.1% had NT-proBNP level ≥160 pg/mL. Of 22 deaths during follow-up, 50% had a TRV ≥3.0 m/s. At 24 months the cumulative survival was 83% with TRV ≥3.0 m/s and 98% with TRV <3.0 m/s. The hazard ratios for death were 11.1 (95% CI, 4.1–30.1; $p < 0.0001$) for TRV ≥3.0 m/s, 4.6 (1.8–11.3; $p = 0.001$) for NT-proBNP ≥160 pg/mL, and 14.9 (5.5–39.9; $p < 0.0001$) for both TRV ≥3.0 m/s and NT-proBNP ≥160 pg/mL.[123]

Several studies have provided insights into PH in SCD using the gold standard diagnostic test for the disease—right heart catheterization (Table 95-2).

TABLE 95-2 Right Heart Catheterization–based Pulmonary Hypertension Screening Studies in Sickle Cell Disease

	Parent	Fonseca	Mehari
Subjects screened (*N*)	398	80	531
Number of subjects with PH	24	8	55
Percentage of screened population	6	10	10.5
mPAP, mm Hg	30 ± 6	33 ± 9	36 ± 9
CO, L/min	9 ± 2	5 ± 2[a]	9 ± 2
PVR, dyn-s/cm^5	138 ± 58	179 ± 120[b]	227 ± 149
6MWD, m	404 ± 94	460 ± 152	358 ± 115
Number of subjects with precapillary PH	11	3	31
Percent of screened population	2.7	3.75	6.0
Number of subjects with postcapillary PH	13	5	24
Percent of screened population	3.3	6.25	4.5
Mortality in PH group	23%	38%	36%

PH, pulmonary hypertension; mPAP, mean pulmonary artery pressure; CO, cardiac output; PVR, pulmonary vascular resistance; 6MWD, 6-minute walk distance.

[a] Cardiac index (L/min/m^2).

[b] Converted mean value: PVR measured in Wood units.

In a screening study of more than 500 patients followed for up to 9 years (median duration of follow-up, 4.4 years),[121] 86 patients underwent right heart catheterization; 56 were diagnosed with PH (defined as mPAP ≥25 mm Hg) (10.5%). Similar findings were observed in another screening study of 80 patients (10% prevalence of PH using right heart catheterization).[118] A large screening study of nearly 400 patients with SCD in France[119] demonstrated a prevalence of PH (determined by right heart catheterization) of 6%.

The presence of PH, as documented by right heart catheterization, is a major risk factor for death in patients with SCD, with mortality rates ranging from 23% to 38%.[118,119,121] In one study, a 50% 2-year mortality rate was reported in patients with PH and SCD.[124] Each increase of 10 mm Hg in mean PAP was associated with a 1.7-fold increase in death rate. Autopsy studies suggest that up to 75% of patients with SCD have histologic evidence of pulmonary arterial hypertension at the time of death (Fig. 95-3).[125]

Finally, specific hemodynamic values independently associated with mortality include increases in mean PAP, diastolic PAP, diastolic PAP–pulmonary capillary wedge pressure gradient, transpulmonary gradient, and pulmonary vascular resistance.[120] These data strongly suggest that mortality in adults with SCD and PH is proportional to the severity of precapillary PH.[120]

■ Pathogenesis

An association between the development of PH and the intensity of hemolytic anemia has been observed in prospective screening studies of adult patients with SCD,[35,116,117,119,121,122] and in an expanding number of pediatric studies.[126–130] The association suggests that hemolysis is related mechanistically to PH.

Hemolysis releases plasma-free hemoglobin that inactivates the intrinsic vasodilator NO[26,27] and arginase 1, which depletes L-arginine, the substrate for NO synthesis.[25] The result of these combined pathologic processes is decreased NO bioavailability

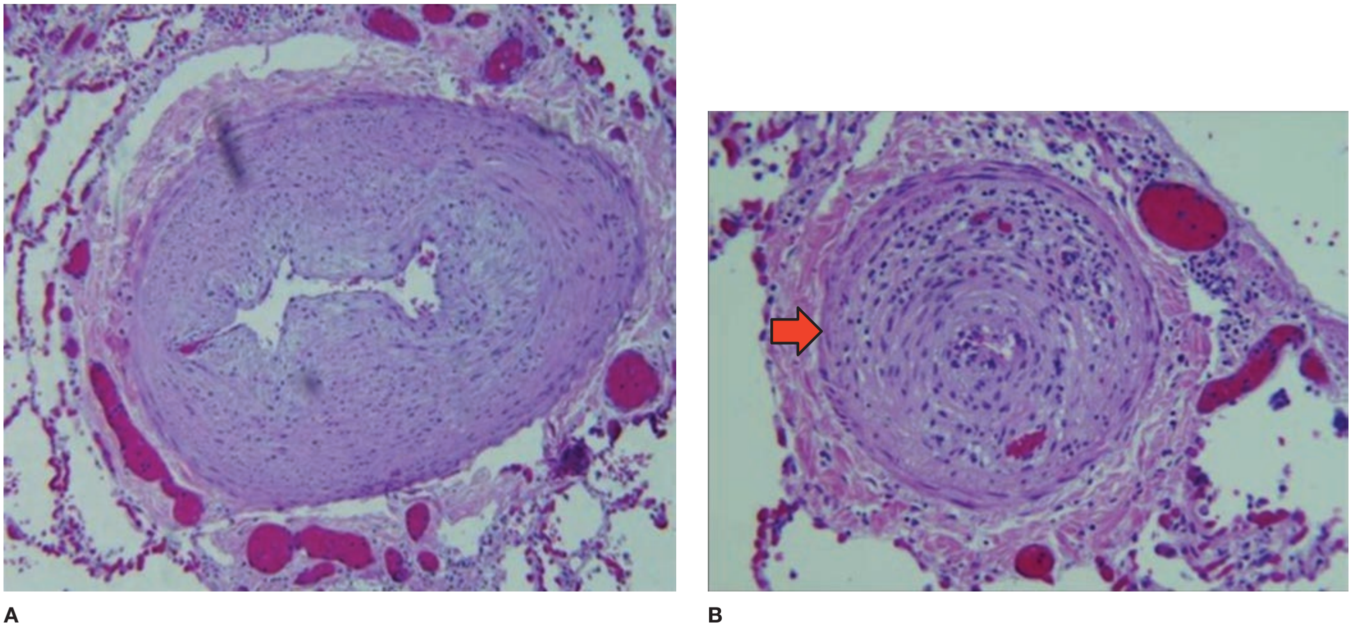


Figure 95-3 Pulmonary arteriopathy in sickle cell-related pulmonary hypertension. **A.** Low power photomicrograph demonstrating intimal and pulmonary arterial smooth muscle hypertrophy (H&E stain). **B.** Plexiform lesion (*arrow*, H&E stain).

and "resistance" to NO-dependent vasodilation.[27] In addition, the accumulation of redox-active heme and iron from lysed red blood cells contributes to the generation of reactive oxygen species that can exacerbate thrombosis and vascular proliferative responses.[131]

In situ thrombosis is well documented in patients with pulmonary arterial hypertension and chronic thromboembolism causes chronic thromboembolic PH (CTEPH). Sickle cell disease is associated with an increased risk for thrombotic complications, including pulmonary embolism[132] and, consequently, CTEPH. A correlation exists between the rate of hemolysis and levels of procoagulant factors in blood in patients with SCD.[133–135] In addition, hemolysis and decreased NO bioavailability induce platelet activation,[136] thrombin generation, and tissue factor activation, which would induce a procoagulant state.[137] Hemolysis is also associated with the formation of red blood cell microvesicles expressing phosphatidylserine, which activates tissue factor, a procoagulant mediator.[135,138] Microthrombotic and/or thromboembolic lesions are common findings at postmortem examination in patients with SCD.[139,140] Acute or organizing thrombi in the pulmonary arteries, predominantly distally, was a common finding at autopsy in a series of 11 sickle cell disease patients with the diagnosis of PH.[141] A significant association was found between the postmortem diagnoses of PH and thromboembolism in another autopsy series.[142]

Splenectomy has been reported to be a risk factor for development of PH,[143] particularly in patients with hemolytic disorders.[144–146] Thus, functional or surgical asplenia may contribute to development of PH in patients with SCD. In addition, loss of splenic function may trigger platelet activation, promoting pulmonary microthrombosis and red cell adhesion to the endothelium.[147] Patients with SCD also have increased levels of cell-free hemoglobin and red cell prothrombotic microvesicles. Following splenectomy, the rate of intravascular hemolysis increases.[135]

Additional mechanisms in the pathogenesis of PH in SCD may be operative. In patients with SCD at clinical baseline or during vaso-occlusive pain crises, plasma endothelin 1 levels are increased.[148] In vitro, sickled erythrocytes increase endothelin 1 production by cultured human endothelial cells. In addition, endothelin receptor A antagonism abolishes the vasoconstrictive effects of media obtained from pulmonary endothelial cells exposed to sickled erythrocytes on aortic rings.[149]

Chronic hypoxia and normoxic activation of hypoxia-inducible factor (HIF)-related pathways are involved in the etiology of various forms of PH.[149–154] Sickle cell disease is characterized by high circulating erythropoietin concentration (which is controlled by HIF-1α, the master regulator the response to hypoxia and which reflects tissue oxygenation status[155]) under steady state conditions,[122] suggesting that this chronic hemolytic anemia is accompanied by chronic upregulation of the hypoxic response. Confirming this hypothesis, Xu et al. compared clinical characteristics and peripheral blood mononuclear cell (PBMC) genomic profiles of subjects with sickle cell disease to those of subjects with Chuvash polycythemia, a monogenic disorder where homozygosity for *VHL*$^{\mathrm{R200W}}$ leads to posttranslational stabilization of the alpha subunits of HIF at normoxia, increased levels of HIF-1 and HIF-2 leading to altered transcription of a number of genes, and elevated systolic pulmonary artery pressures.[156–158] Results showed a strong correlation of altered gene expression profiles in SCD subjects and subjects with Chuvash polycythemia, suggesting that more than 50% of PBMC gene expression variation in hemoglobin SS patients may be related to the hypoxic response.[159] Interestingly, *MAPK8,* a hypoxia-downregulated gene that has a prominent role in promoting apoptosis,[160] appeared to play an important role in hypoxic gene regulation—and an eQTL of this gene (rs10857560) that further downregulated expression was associated with right heart catheterization–documented precapillary PH in SCD. Further, in another study, elevated levels of placental growth factor which activates HIF-1α in normoxia have been shown to be elevated and associated with elevated systolic pulmonary artery pressures in sickle cell disease mice and patients.[161,162]

Single-nucleotide polymorphisms for genes in the TGF-β superfamily—including activin A receptor, type II-like 1 (*ACVRL1*); bone morphogenetic protein receptor 2 (*BMPR2*); bone morphogenetic protein 6 (*BMP6*); the beta-1 adrenergic receptor (*ADRB1*);[163] and thrombospondin-1 (*THBS1*)[164]—have been associated with an elevated pulmonary artery systolic pressure in patients with SCD. Desai et al.[165] explored the usefulness of PBMC-derived gene signatures as biomarkers for PH in SCD. Genome-wide gene and micro-RNA (miRNA) expression profiles were correlated against estimated right ventricular systolic pressure (RVSP), yielding 631 transcripts and 12 miRNAs correlating with RVSP. Biological pathway analysis of these 631 genes revealed that pathways that have been associated with pulmonary vascular remodeling such as Wnt signaling, calcium signaling, vascular smooth muscle contraction, and cancer pathways were significantly overrepresented in subjects with elevated RVSP. Support vector machine analysis identified a 10-gene signature including *GALNT13* (encoding polypeptide *N*-acetylgalactosaminyltransferase 13, a glycosyltransferase enzyme responsible for the synthesis of O-glycan) that distinguished patients with and without increased RVSP with 100% accuracy. This finding was then validated in a separate cohort of patients who had sickle cell disease without or with PH documented by right heart catheterization, with an overall accuracy of 90%. Increased RVSP-related miRNAs revealed strong in-silico binding predictions of miR-301a to *GALNT13*, which was corroborated by microarray analyses demonstrating an inverse correlation between their expression. A genetic association study comparing patients with elevated or normal RVSP revealed five significant single-nucleotide polymorphisms within *GALNT13* associated with an elevated RVSP.

Finally, in theory, a high pulmonary artery pressure may result from the high cardiac output state associated with chronic anemia in SCD. However, this hyperdynamic state does not appear to be a major contributor to significant elevations in pulmonary artery pressure, as reports of PH associated with nonhemolytic anemias are lacking. Conceivably, a high cardiac output state, combined with hemolytic anemia and other risk factors, such as renal insufficiency and iron overload, conspire to drive pathologic pulmonary vascular remodeling.

■ Clinical Features and Evaluation

The diagnostic evaluation of patients with SCD suspected of having PH should follow the same guidelines established for other causes of PH.[166,167] Given the high prevalence of PH in this population and the associated high mortality, guidelines form the American Thoracic Society recommend universal noninvasive screening of all adults using Doppler echocardiography, measurement of steady-state plasma NT-proBNP levels, and assessment of functional capacity to assess the risk of death and of having PH for further diagnosis and intensification of sickle cell–specific therapies.[41] In patients with SCD, the echocardiographic estimation of PASP ($\text{PASP} = 4 \times \text{TRV}^2 +$ estimate of the central venous pressure) correlates well with measured PASP by right heart catheterization.[35] While no prospective data on prevalence and risk of PH are available for children, we currently recommend that children with hypoxemia, high hemolytic rate (hemoglobin values <7 g/dL and high LDH), or recurrent ACS be screened. Importantly, screening should be performed in the steady state, as pulmonary artery pressures rise during vaso-occlusive painful crises.[168]

The Doppler echocardiogram is an important tool for population screening and estimation of pulmonary artery pressure, but it cannot be used to diagnose or define PH, which is based on measurement of mPAP via right heart catheterization. In order to identify a subgroup of patients with SCD who are at a high risk for a diagnosis of PH as well as very high risk of death and hospitalization, we have analyzed data from both the NIH-PH screening study[169–171] and the Walk-PHASST cohort[123,172–174] using TRV and NT-proBNP values as noninvasive screening tests. Elevation of both of these parameters improves the positive predictive value of the echocardiogram to diagnose PH to approximately 62%[175] and identifies a group at higher risk of death. The prevalence of TRV ≥ 2.5 m/ss *and* an NT-proBNP ≥ 160 pg/mL was 19.2% in adults screened in the Walk-PHASST trial. This prevalence was 19.4% in adult patients in NIH-PH screening cohort. In the Walk-PHASST study, the 12-month mortality rate is 7.9% in this group compared with 0.5% in patients with normal TRV or NT-proBNP values. In the NIH-PH cohort these rates were 8.6% and 0.7%, respectively. This patient population is also at higher risk of hospitalization, with a risk ratio for hospitalization of 1.73. In the Walk-PHASST cohort, 12-month hospitalization risk was 78% for patients with abnormal TRV and NT-proBNP values (high-risk group) compared with 45% for patients with normal TRV or BNP values (low-risk group). This analysis suggests that a simple screening profile of TRV and NT-proBNP can identify about 19% of patients with SCD at the highest risk of death and hospitalization. Based on these data, we propose a PH-screening algorithm for adult patients with SCD (Fig. 95-4).

The diagnosis of PH in patients with SCD may be challenging (Fig. 95-5). Exertional dyspnea, the most typical presentation of PH, is also a cardinal symptom of chronic anemia and other conditions commonly present in patients with SCD, such as left ventricular dysfunction, pulmonary fibrosis, and cirrhosis. Therefore, a high index of suspicion for diagnosis is necessary.

Patients with SCD and PH tend to be older and have higher systolic arterial blood pressure, lower hemoglobin levels, higher indices of hemolysis, lower hemoglobin–oxygen saturation, greater degrees of renal and liver dysfunction, and higher numbers of lifetime red blood cell transfusions.[35] Diagnostic evaluation should also include an aggressive search for other conditions that might contribute to PH, such as iron overload, chronic liver disease, HIV infection, nocturnal hypoxemia, and pulmonary thromboembolism. A diagnostic right heart catheterization is essential to confirm the diagnosis and to exclude diastolic dysfunction.[166] The 6-min walk test is a useful surrogate for assessing functional capacity in this patient population and inversely correlates with the severity of PH.[176] In spite of this correlation, important to note is that in patients with SCD, noncardiopulmonary factors, such as concurrent pain and avascular necrosis of the hip, can interfere with test performance.

Measurement of NT-proBNP levels may be used as a PH biomarker for diagnosis and risk stratification in patients with SCD.[13] NT-proBNP levels are higher in patients with sickle cell–associated PH and correlate directly with the severity of PH and degree of functional impairment. An NT-proBNP level of 160 pg/mL or greater is associated with PH and is an independent predictor of mortality (risk ratio, 5.1; 95% CI, 2.1–12.5; $p < 0.001$).[13]

Most adult patients with SCD develop abnormal pulmonary function characterized by mild restriction (mean TLC approximately 79% of predicted), abnormal diffusing capacity, and radiographic signs of mild pulmonary fibrosis.[10,177–181] The severity of the defects seems to be slightly greater in those patients with PH.[176] However, in these patients, the degree of pulmonary function abnormalities is rarely severe enough to be a major contributor to the etiology of the PH.

A ventilation–perfusion scan is an indispensable component of the evaluation, since chronic pulmonary thromboembolic disease, if amenable to pulmonary endarterectomy, is a potentially curable form of PH in patients with chronic hemolytic disorders. In the majority of cases, observed scintigraphic evidence of thromboembolic disease is uncommon; the most commonly seen abnormalities are patchy areas of abnormal perfusion, similar to findings described in other forms of PH.[176,182] However, scintigraphic evidence suggestive of chronic thromboembolic PH occurs in approximately 5% of patients with SCD and severe PH,[168] and the PH has been successfully treated surgically in two patients (Fig. 95-6).[183] Consequently, patients should undergo imaging studies, and if findings are suggestive of chronic thromboembolic PH, additional invasive studies (i.e., angiography) are warranted to exclude a potentially surgically treatable condition.

■ Hemodynamic Profiles and Etiology of Pulmonary Hypertension in Sickle Cell Disease

Because of the different presentations, PH in the setting of sickle cell disease is currently listed in group 5 (a miscellaneous category that

includes the hemolytic anemias).[114] As such, patients with sickle cell disease have been shown to develop PH with primary involvement of the pulmonary vasculature (group 1 PH or pulmonary arterial hypertension [PAH]), secondary to left heart disease (group 2 PH), secondary to interstitial lung disease or pulmonary fibrosis (group 3 PH), and secondary to chronic thromboembolic disease (CTEPH or group 4 PH). From a hemodynamic and anatomic perspective groups 1, 3, and 4 PH are also defined as precapillary PH characterized by normal left heart filling pressures (pulmonary artery wedge pressure or left ventricular end-diastolic pressure <15 mm Hg), and group 3 PH is defined as postcapillary PH characterized by elevated left heart filling pressures (pulmonary artery wedge pressure or left

ventricular end-diastolic pressure >15 mm Hg). Combined pre- and postcapillary PH is defined as mPAP >20 mm Hg, PAWP/LVEDP is ≥ 15 mm Hg, and pulmonary vascular resistance >3 Wood Units.

As previously discussed, as hemoglobin level decreases cardiac output increases, filling pressures tend to decrease, and systemic and pulmonary vascular resistances decrease. In studies of patients with SCD undergoing right heart catheterization, the mean cardiac output and pulmonary vascular resistance for patients without PH were 10 L/min and 59 $\text{dyn} \cdot \text{s/cm}^5$, respectively.[40,124,176] It is within the context of these data that one must consider the impact of PH in chronically anemic patients with hemolytic disorders. As such, we believe that it is appropriate to consider a lower upper limit of "normal" pulmonary vascular resistance (such as <160 $\text{dyn} \cdot \text{s/cm}^5$) in these patients.

In contrast to patients with traditional forms of pulmonary arterial hypertension (e.g., idiopathic, scleroderma associated), who are symptomatic with mean pulmonary arterial pressures in the range of 50 to 60 mm Hg, in patients with SCD the degree of elevation in mean pulmonary pressures is mild to moderate, in the range of 30 to 40 mm Hg, with mild elevations in pulmonary vascular resistance.[40,118,119,121,124,176] These patients also have coexistent mild elevation in pulmonary capillary wedge pressure, suggesting left heart failure.[40,118,119,121,124,176]

Right heart catheterization data from these multiple studies using the previously accepted definition of PH show that the hemodynamic etiology of the PH in patients with SCD is multifactorial: precapillary pulmonary hypertension (precap PH, defined by mPAP $\geq$25 mm Hg and wedge pressure $\leq$15 mm Hg) is present in 50% of catheterized patients, while postcapillary pulmonary hypertension secondary to left ventricular diastolic dysfunction (postcap PH, defined by mPAP $\geq$25 mm Hg and wedge pressure $>$15 mm Hg) is present in 50%.

■ Heart Failure with Preserved Ejection Fraction

In response to chronic anemia, the left ventricle responds with an increase in stroke volume and chamber dilation. This response leads to increased wall stress and an increase in left ventricular mass that, in turn, leads to impaired filling, which characterizes diastolic dysfunction and a syndrome of heart failure with preserved ejection fraction. In patients with SCD, elevated systemic systolic blood pressure is an independent risk factor for the development of pulmonary hypertension, hypoxemia, diastolic heart dysfunction, chronic kidney injury, silent infarcts, and ischemic stroke.[184–187] Both anemia and increases in blood pressure are risk factors for the development of left ventricular diastolic dysfunction in patients with SCD.[185,188] Using echocardiography in a cohort of 141 patients, Sachdev et al. found that 47% had a high TRV, diastolic dysfunction, or both (29% had a high TRV alone, 11% had diastolic dysfunction and a high TRV, and 7% had diastolic dysfunction alone). An elevated TRV and diastolic dysfunction were associated with a relative risk of death of 5.1 (95% CI, 2.0–13.3) and 4.8 (95% CI, 1.9–12.1), respectively, while the relative risk of death when both were present was 12.0 (95% CI, 3.8–38.1), suggesting that both PH and diastolic dysfunction independently carry additive mortality risk.[189] In addition, in a series of 483 patients with homozygous SCD, markers of diastolic dysfunction were independently associated with a low 6-min walk distance and increased mortality.[122] A high prevalence of diastolic dysfunction has also been reported in pediatric cohorts, but mortality in all pediatric patients is exceedingly low, and it is not clear if these patients progress with age to more severe disease.[190–192]

■ Effects of Pulmonary Hypertension on Exercise Capacity

Patients with SCD appear to be poorly tolerant of even small additional increases in pulmonary artery pressure and pulmonary vascular resistance. When compared with age-, gender-, and hemoglobin-matched patients with SCD without PH, individuals with PH and mPAP of 36 mm Hg exhibit lower 6-min walk distance (435 ± 31 vs. 320 ± 20 m; $p = 0.002$) and peak oxygen consumption (50 ± 3% vs. 41 ± 2% of predicted; $p = 0.02$) and higher ventilatory equivalent for CO_2 at anaerobic threshold (31.6 ± 1.5% vs. 39.2 ± 1.6; $p = 0.035$) on cardiopulmonary exercise testing (Chapter 34).[176] In that study, the 6-min walk distance was inversely correlated with pulmonary vascular resistance and mPAP, and directly correlated with maximal oxygen consumption, supporting the contribution of increasing pulmonary artery pressures to loss of exercise capacity. A lower exercise capacity (assessed by the 6-min walk test) in patients with PH has also been demonstrated in larger cohorts of patients with SCD.[118,119,121,122] In addition, in patients with SCD, pulmonary artery pressure and pulmonary vascular resistance sharply rises with exercise, suggesting that pulmonary vascular disease contributes to functional limitation in these patients.[168] In aggregate, these data suggest that in patients with chronic anemia, mild to moderate PH has a severe adverse impact on functional and aerobic exercise capacity.

■ Treatment

There are limited data on the specific management of patients with SCD and PH, and most treatment recommendations are based on expert opinion or extrapolated from data derived from other forms of PH.[193] The general approach should include maximization of SCD-specific therapy (i.e., treatment of primary hemoglobinopathy), treatment of hypoxia with chronic oxygen therapy, and treatment of associated cardiopulmonary conditions (such as iron overload, chronic liver disease, HIV infection, nocturnal hypoxemia, thromboembolic disorders, and left ventricular disease). In patients with SCD with PAH (mean PAP $\geq$25 mm Hg and wedge pressures $<$15 mm Hg, with a relatively high pulmonary vascular resistance, e.g., $>$160 dyn • s/cm^5), PAH-specific therapy can be considered. There are no long-term data on the specific treatment of PH in SCD, and the choice of agents is largely empirical and based on the safety profile of the drugs and physician preference. Therapy should be initiated and monitored by a team composed of a PAH specialist and a hematologist specializing in SCD care.

Hydroxyurea has been shown to decrease the incidence of pain episodes and ACS, to reduce the need for transfusions, and to lower overall mortality.[12,79] It is possible that some of the decreases in pulmonary and cardiovascular deaths seen in hydroxyurea-treated patients could be related to an improvement in PH. However, these considerations have to be balanced with the lack of association between fetal hemoglobin levels and the use of hydroxyurea, and protection against the development of PH.[35] For patients with creatinine levels less than 1 mg/dL, hydroxyurea is started at a dose of 15 mg/kg/d and titrated up to a maximum of 35 mg/kg/d. Recent detailed treatment guidelines have been published.[80,194] Patients with renal dysfunction tend not to tolerate the myelosuppressant effects of hydroxyurea. In those cases, we recommend the addition of erythropoietin to the regimen. Long-term transfusion therapy lowers the risks of most complications of the disease, including the risks of pulmonary events and central nervous system vasculopathy.[195–197] It might improve cardiopulmonary function and prevent the progression of PH.[198] The same concepts and potential benefits might apply to stem cell transplantation, which has been shown to normalize pulmonary pressures and to improve short-term outcome measures in one patient.[199] There is insufficient evidence to determine the efficacy of L-glutamine,[83] voxelotor,[84] and crizanlizumab[85] in the prevention or treatment of PH associated with SCD.

The potential benefits of warfarin therapy observed in patients with idiopathic pulmonary arterial hypertension[200] have to be weighed against the risk of hemorrhagic stroke in adults with SCD or hemorrhage in chronically anemic individuals. We believe that the relatively low risk of hemorrhagic stroke (0.21 events per 100 patient-years[201]) compared with the high risk of death in patients with severe PH supports anticoagulation in patients with hemodynamic evidence of pulmonary arterial hypertension or chronic thromboembolic PH and without a specific contraindication.

Sildenafil and other phosphodiesterase 5 inhibitors function by inhibiting the metabolism of cyclic guanosine monophosphate, the second messenger that mediates the effects of NO. In a series of 7 patients with either thalassemia or sickle thalassemia and severe PH, treatment with sildenafil from 4 weeks to 48 months resulted in an improvement in TRV, New York Heart Association functional class, and 6-min walk distance.[202] In another case series, 12 patients with SCD were treated with sildenafil for a mean of 6 months. Mean PASP decreased by 9 mm Hg (95% CI, 0.3–17; $p = 0.047$), 6-min walk distance improved by 78 m (95% CI, 40–117; $p = 0.003$), and mean BNP decreased by 448 pg/mL ($p = 0.002$).[203] These preliminary data were not supported by the results of the Walk-PHaSST study.[204] This 16-week, NIH-sponsored, multicenter, double-blind, placebo-controlled trial of sildenafil in 74 patients with SCD with increased TRV and a low exercise capacity was stopped early, before enrollment of the planned 132 patients, due to a higher percentage of subjects experiencing serious adverse events in the sildenafil arm (45% of sildenafil, 22% placebo; $p = 0.022$). Subject hospitalization for pain was the predominant cause for this difference: 35% sildenafil versus 14% placebo ($p = 0.029$). Although the study was underpowered at the time it was stopped, there was no evidence of a treatment effect on 6MWD (placebo-corrected effect, −9 m; 95% CI, −56 to 38; $p = 0.703$), TRV ($p = 0.503$), or NT-proBNP ($p = 0.410$). Based on these findings, sildenafil and the other PDE5 inhibitors should not be used as first-line agents in patients with SCD and PAH. If used, sildenafil should be used only in patients on chronic transfusion therapy or very well controlled with hydroxyurea, to limit the apparent effects of these agents on increasing pain.

Riociguat is a small molecule activator of the soluble guanylate cyclase enzyme, which is approved for the treatment of pulmonary arterial hypertension and CTEPH.[205] Weir et al.[206] reported on the use of riociguat in six patients with SCD and CTEPH. In this limited series, use of riociguat was not associated with an increase in episodes of SCD-related pain, although one patient discontinued the drug due to intractable headaches. Treatment with riociguat resulted in improvements in functional class, exercise capacity, NT-proBNP levels, and estimated RVSP in three of the patients.

The published experience with endothelin receptor antagonists in the treatment of PH is also very limited. Minniti et al.[207] reported on the use of bosentan and ambrisentan in a cohort of 14 patients with SCD and PH documented by heart catheterization. Endothelin antagonist therapy either as monotherapy or in combination with sildenafil resulted in a modest improvement in 6-min walk distance (baseline 357 ± 22 vs. 398 ± 18 m 6 months posttherapy; $p < 0.05$) as well as lowered NT-proBNP levels and estimated PASP. Adverse events while on therapy occurred in 7 of 14 patients, including increased serum alanine aminotransferase (2), increased peripheral edema (4), rash (1), headache (1), and decreased hemoglobin (2). Only 2 patients required treatment discontinuation, and few patients experienced multiple side effects. Two randomized multicenter placebo-controlled studies evaluating the role of endothelin receptor antagonism in patients with SCD have been conducted. The ASSET-1 and ASSET-2 studies enrolled patients with pulmonary arterial hypertension and pulmonary venous hypertension, respectively, who were randomized to bosentan or placebo. After enrollment of 26 subjects the studies were terminated due to slow site activation and withdrawal of support by the sponsor. In that limited sample of patients, bosentan was well tolerated with no significant differences in serious adverse events or laboratory tests between patients receiving study drug or placebo, but efficacy endpoints could not be formally analyzed.[208]

Prostanoid analogs are the most effective agents for the treatment of pulmonary arterial hypertension. Acute administration of epoprostenol decreases pulmonary artery pressure and pulmonary vascular resistance and increases cardiac output in patients with PH and SCD.[124] Chronic prostacyclin-based therapy has been shown to reduce pulmonary pressures, increase 6-min walk distance, and improve functional class in a case series of patients with sickle cell disease and pulmonary hypertension.[209] A case of severe pulmonary arterial hypertension related to pulmonary veno-occlusive disease has been reported in a patient with SCD. This patient failed medical therapy and underwent a successful bilateral lung transplantation.[210]

RESTRICTIVE LUNG DISEASE

Repetitive episodes of acute lung injury related to the ACS can result in parenchymal damage and restrictive lung disease (Fig. 95-7). In a study of 310 patients with homozygous SCD, pulmonary function was abnormal in 90% of adult patients.[211] The most common abnormal pattern was a mild restrictive pattern, found in 74% of those patients (TLC of 70 ± 15% predicted). An isolated decreased $D_{L_{CO}}$ was found in 13% (57 ± 20% predicted), persisted when corrected for hemoglobin, and negatively correlated with age. Evidence of obstructive lung disease occurred in only 3% of those studied. Although patients may present with advanced interstitial lung disease, these findings suggest that pulmonary fibrosis secondary to recurrent episodes of ACS tends to be mild in most cases.

SLEEP-DISORDERED BREATHING

Sleep-disordered breathing has been reported in both children and adults with SCD.[212–214] In children, sleep-related upper airway

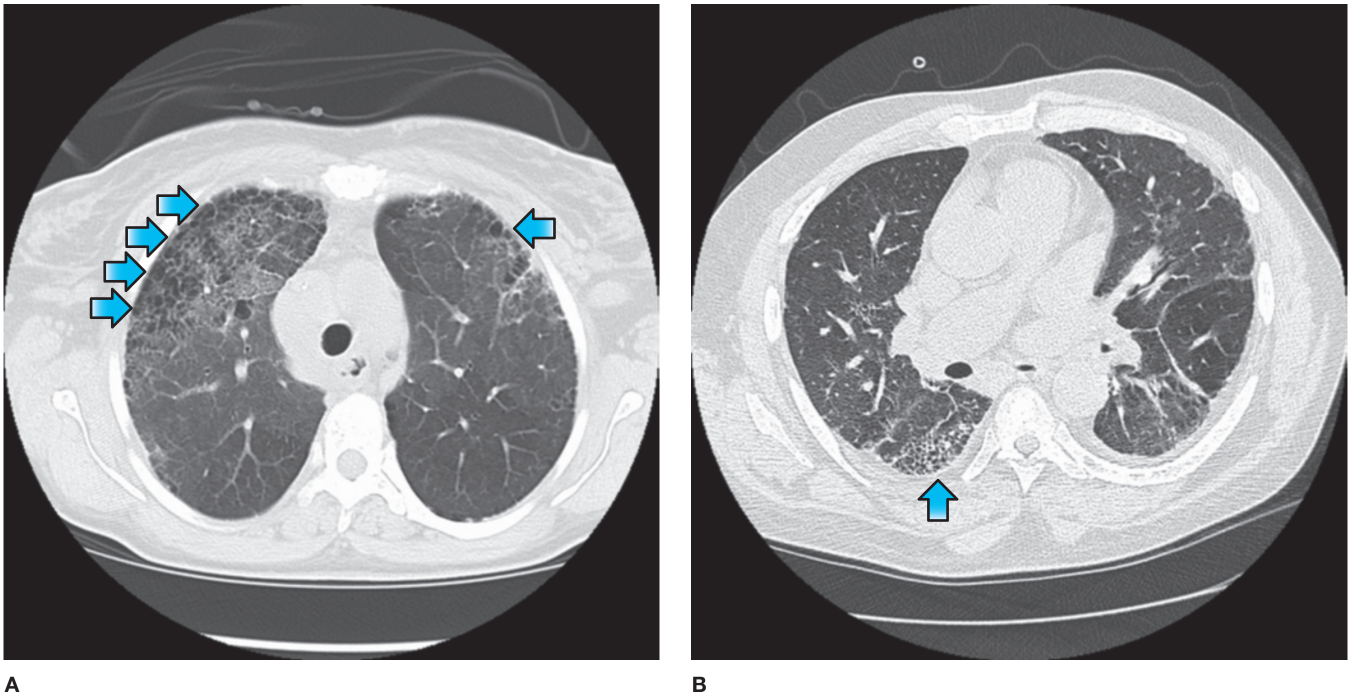

Figure 95-7 Pulmonary fibrosis *(blue arrows)* complicating multiple episodes of acute chest syndrome. **A.** Cystic changes in areas of fibrosis. **B.** Subpleural fibrosis with honeycombing. *(Reproduced with permission from Miller AC, Gladwin MT. obstruction and hypoxemia are the most common disturbances. In an uncontrolled study, adenotonsillectomy led to symptomatic improvement and amelioration of oxygen desaturation.[215,216] A small study of autoadjusting continuous positive-airway pressure (auto-CPAP) with supplemental oxygen also suggests that this therapeutic modality is well tolerated, safe, and effective in pediatric patients with SCD.[217]

Several lines of evidence suggest that nocturnal hypoxemia contributes to the development of neurologic events and vaso-occlusive crisis via mechanisms that could involve upregulation of several inflammatory endothelial adhesion molecules.[218–220] In addition, nighttime oxygen desaturation is associated with an increase in left ventricular mass and impaired diastolic function as evidenced by a study of 44 children with SCD.[221] However, in a recent prospective study of 140 children with SCD followed for a median of 4.9 years, a low nocturnal oxygen saturation, higher obstructive AHI, and higher oxygen desaturation index were not associated with increased incidence of acute severe pain episodes.[222]

SUMMARY AND CONCLUSIONS

Pulmonary complications are a major cause of morbidity and mortality in patients with SCD, and the burden of these complications is likely to become more prevalent as the life expectancy of these patients continues to increase.

Among the acute complications, ACS, which is often complicated by right heart failure, remains a major cause of death in children and adults with SCD. Fortunately, current strategies of early aggressive supportive therapy with antibiotics and red blood cell transfusion appear to have improved outcomes when compared with historic data.

PH is common and the most significant cause of death in adults with SCD. Although the etiology of PH is multifactorial in these patients, pulmonary arterial hypertension appears to be the main driver of morbidity and mortality. Additional studies evaluating pulmonary arterial hypertension–targeted therapy are needed in this complex and high-risk population.

CHAPTER 96

Pulmonary Disorders and Pregnancy

Ghada Bourjeily

INTRODUCTION

Global fertility rates are predicted to drop significantly by 2100[1] but despite lower birth rates, there remains high maternal mortality worldwide. While the maternal mortality rate has declined since the turn of the century, approximately 810 women die of preventable pregnancy- and childbirth-related complications daily.[2] Younger women and those residing in low- and middle-income countries have a disproportionately higher risk of maternal death. Meanwhile, globally, there has been a steady rise in women becoming pregnant later in their reproductive lives,[3] particularly in higher-income countries. Together, this highlights significant inequities in the childbearing experience for women around the world. Increased maternal age is due to many factors, including more women in the workforce than ever before, and advances in assisted reproductive technology that have allowed women who might otherwise be infertile to achieve a pregnancy. Additionally, reproductive medicine now helps many women with chronic medical conditions to become pregnant. Consequently, pregnant women are now older and have more comorbid conditions than in past generations. Given the dramatic physiologic changes that occur during gestation, pregnancy can have significant clinical consequences especially among women with chronic cardiopulmonary disease.

Labor and delivery constitute a major hemodynamic and respiratory challenge; hence, women with either acute or chronic respiratory conditions need to be managed by a multidisciplinary healthcare team, which should include a pulmonologist. This multidisciplinary team should address medical and obstetric concerns, along with risks and benefits of anesthesia and analgesia, thereby ensuring appropriate management and anticipation of potential complications for both the mother and her newborn. This chapter addresses core pulmonary and cardiovascular physiologic concepts and then examines important, common clinical entities related to pulmonary and critical care diagnoses and clinical management in pregnancy.

THE PHYSIOLOGY OF PREGNANCY

While the normal physiologic changes of pregnancy are extensive, several areas are of central importance and are considered below. These include changes in respiratory and cardiovascular physiology, normal physiologic developments during labor and delivery, and determinants of fetal oxygenation and ventilation.

Respiratory Physiology

During pregnancy, the respiratory system undergoes changes throughout the respiratory tract. The effects of increasing levels of estrogen on the nasal mucosa can include edema, hyperemia, and glandular hypersecretion, which may result in gestational rhinitis, typically in the last few weeks of pregnancy.

The subcostal angle of the rib cage and the circumference of the chest wall increase[4] and the diaphragm moves cranially about 4 to 5 cm.[5] Diaphragm excursion does not decrease in pregnancy, despite the changes in chest wall configuration. However, due to the higher resting position of the diaphragm, the decreased downward pull of the abdomen, and the aforementioned chest wall changes, functional residual capacity (FRC) decreases by 20% to 30% by late gestation[6] and declines further in the supine position (Table 96-1).[7] The reduction in FRC may not be reflected when measured using body plethysmography,[8] likely due to the effect of early airway closure during tidal breathing and air trapping.[9] Inspiratory capacity increases, and therefore total lung capacity (TLC) is not significantly changed (Fig. 96-1).[10]

TABLE 96-1 Physiologic Changes in Pregnancy

Respiratory Parameter	Change	Normal Range in Pregnancy
Arterial blood gas values		
pH	↑	Mild respiratory alkalosis
Pa$_{O_2}$	↑	Average 100–105
Pa$_{co_2}$	↓	Average 28–32
HCO$_3$	↓	18–22 mEq/L
Alveolar–arterial O$_2$ gradient	↑	Increase in late gestation to approximately 20 mm Hg
Oxygen consumption	↑	20% increase, further increase during labor and delivery
Minute ventilation	↑	50% increase
Respiratory rate	↔	No change
Tidal volume	↑	40%–50% increase
Total lung capacity	↓	4%–5% decrease
Functional residual capacity	↓	20% decrease by term
Residual volume	↓	
Vital capacity	↔	
Diffusion capacity	↔	Minimal change
Forced expiratory volume in 1 s	↔	
Peak expiratory flow rate	↔	
Cardiac	**Change**	**Normal Range in Pregnancy**
Blood pressure	↓	10- to 15-mm Hg decrease in first two trimesters
Blood volume	↑	30%–50% increase
Cardiac output	↑↑	5–7 L/m^2/min (40% increase)
Central venous pressure	↔	<13 mm Hg
Colloid oncotic pressure	↓	10%–15% decrease
Ejection fraction	↔	70%
Heart rate	↑	Increases by 10–20 bpm
Pulmonary artery pressure	↔	≤25 mm Hg
Pulmonary capillary wedge pressure	↔	<13 mm Hg
Stroke volume	↑	70–100 mL/beat
Systemic vascular resistance	↓	25%–30% decrease

↑ Increase, ↓ Decrease, ↔ No change.

Figure 96-1 Changes in lung volumes in pregnancy. *(Reproduced with permission from Hegewald MJ, Crapo RO. Respiratory physiology in pregnancy. Clin Chest Med. 2011;32(1):1–13.)*

Despite a reduction in FRC and reduced nasopharyngeal caliber, air flow rates and airway resistance do not change in pregnancy, since pregnancy is associated with bronchial smooth muscle relaxation.[11] While the increased cardiac output of pregnancy (see "Cardiovascular Physiology," below) may increase diffusion capacity, the associated anemia of pregnancy offsets this effect. DL_{CO} is higher in the first trimester (after correcting for alveolar volume and hemoglobin), but it may decline later in pregnancy, reaching a nadir at about 24 to 27 weeks' gestation.[12]

Oxygen consumption increases in pregnancy, and minute ventilation increases by about 50%. This increase is achieved by an increase in tidal volume and mediated in part by higher levels of progesterone, a known respiratory drive stimulant. Although some studies suggest a progressive increase in minute ventilation during the course of pregnancy,[6] most studies show a sharp increase in the first trimester, with minimal rise after that.[13,14] The ratio of dead space to tidal volume (V_D/V_T) is unchanged in pregnancy, suggesting that dead space is actually also increased. While the increase in cardiac output and the resultant improved perfusion of the lung apices seen in pregnancy should result in a reduction in dead space, many studies suggest the opposite effect.[15,16]

Arterial oxygen tension increases in pregnancy to about 100 to 105 mm Hg, thereby facilitating oxygen transfer across the placenta.[16] Carbon dioxide tension decreases in pregnancy to 27 to 32 mm Hg, with a resultant increase in bicarbonate excretion and elevation in arterial pH to approximately 7.42 to 7.46. Both Pa_{CO_2} and HCO_3 are mildly lower in the third trimester compared with the first trimester.[17] The chronic respiratory alkalosis of pregnancy causes a rightward shift of the oxyhemoglobin dissociation curve, also facilitating oxygen transfer across the placenta.

■ Cardiovascular Physiology

In parallel with growth of the fetus and the accompanying increase in maternal oxygen consumption, pregnancy is accompanied by profound cardiovascular changes. Plasma volume and cardiac output progressively increase throughout gestation and are approximately 30% to 50% higher[18] at term (Fig. 96-2).[19] Heart rate also increases by 20 to 30 beats per minute. Systemic vascular resistance decreases. Historically, blood pressure has been described to decrease in the first half of pregnancy, reaching a nadir in the second trimester. However, recent large cohorts that closely monitored blood pressure in low-risk pregnancies have demonstrated no significant drops in blood pressure values.[20] Despite the increase in cardiac output, pulmonary artery pressures do not change significantly[21] due to a decrease in pulmonary vascular resistance (PVR). Oxygen consumption is increased approximately 20% above prepregnancy levels; the rate of increase in oxygen consumption is faster in pregnant women compared with nonpregnant women performing weight-bearing exercises.[22]

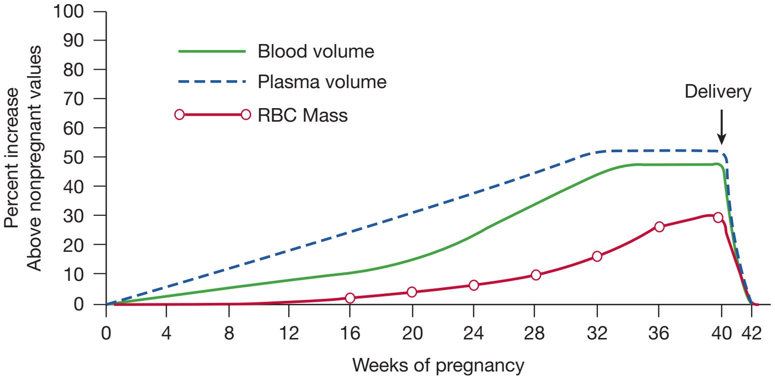

Figure 96-2 Physiologic changes in blood volume, plasma volume, and erythrocyte mass in pregnancy.

■ Labor And Delivery

Labor and delivery are associated with additional respiratory and cardiac physiologic changes. Pain, due to contractions and anxiety, leads to further increases in oxygen consumption and minute ventilation. Increased minute ventilation leads to further reduction in Pa_{CO_2}, which in cases of tenuous placental reserve may reduce placental perfusion. Pain control may help minimize these effects; however, the use of systemic opiates can lead to respiratory depression and needs to be monitored closely. Targeted regional anesthesia, which does not affect the respiratory muscles, may be a beneficial alternative and can help mitigate the stressor on the cardiorespiratory systems. In addition, in women with poor respiratory reserve, such as those with poorly controlled asthma, cystic fibrosis, or interstitial lung disease, the additional increase in minute ventilation may lead to respiratory decompensation and respiratory failure. Physiologic changes occurring in pregnancy quickly reverse in the postpartum period.

Cardiovascular changes in labor, delivery, and the postpartum period include an additional 10% to 15% increase in cardiac output in early labor, with further increases of up to 50% in the second stage of labor.[23] The changes are mediated by autotransfusion, in which 300 to 500 mL of blood is shunted into the systemic maternal circulation with every uterine contraction,[24] and by pain and anxiety.[25,26] Analgesia attenuates the changes. In addition, in the postpartum period, relief of aortocaval compression by the uterus results in an increase in venous return; autotransfusion from the contracting uterus further increases cardiac output. Women with underlying cardiac or pulmonary vascular disease may not tolerate the physiologic changes of labor and delivery. Although scheduled cesarean-section deliveries may appear to be an appropriate option for women with chronic pulmonary or cardiac disease (since they may eliminate the pain and anxiety of contractions), cesarean-section deliveries are unlikely to improve outcomes, since autotransfusion occurs with both vaginal and operative deliveries. Furthermore, the immediate fluid shifts that occur in the postpartum period are similar with both vaginal and cesarean-section deliveries. Operative deliveries are also associated with higher rates of surgical and medical complications when compared with vaginal deliveries.

■ Fetal Oxygenation and Ventilation

Uterine blood flow constitutes about 17% of the total cardiac output.[27] The placental vessels are low-resistance, high-capacitance vessels that function at maximal capacity at baseline. Therefore, when a hemodynamic insult occurs, the placental circulation cannot further vasodilate.

Supine positioning in late pregnancy may be associated with significant reduction in cardiac output and may alter the uterine circulation. Fetal oxygenation, like oxygenation of maternal organs, depends on maternal cardiac output, maternal oxygenation, and the fetal oxyhemoglobin dissociation curve. In addition, characteristics of the placenta affect diffusion of oxygen across this organ.

The fetus displays many protective mechanisms for maintaining adequate oxygenation. For example, fetal hemoglobin, which lacks beta chains, is less sensitive to the effects of 2,3-diphosphoglyceric acid than is adult hemoglobin. Consequently, the fetal oxyhemoglobin dissociation curve is shifted to the left, reflecting an increased oxygen affinity. The fetus also appears to have the ability to shunt blood to vital organs and to decrease oxygen consumption during periods of hypoxia. Despite these protective mechanisms, placental health has an important role in effecting oxygen transport to the fetus.[28]

Clinical conditions that cause a reduction in cardiac output or uterine blood flow (e.g., shock, use of vasoconstricting drugs), oxygen content (e.g., anemia, hypoxemia), oxyhemoglobin saturation (e.g., severe alkalosis, presence of carboxyhemoglobin), or placental perfusion may result in poor fetal oxygenation. Human studies on the optimal maternal oxygen level needed to achieve favorable fetal oxygenation are scarce. Based on extrapolation from available animal data, experts recommend that maternal oxygenation be maintained above a Pa_{O_2} of 70 mm Hg with an oxygen saturation of greater than 95%. However, more recent data from large cohorts suggest that maternal daytime oxygen saturation may drop as low as 93% without associated pathology.[20]

Finally, a gradient for CO_2 of approximately 10 mm Hg between fetal and maternal circulations exists (higher level in the fetus), facilitating CO_2 clearance from the fetal circulation. This fact may influence how best to use permissive hypercapnia in patients who might benefit from this ventilatory strategy. Fetal hypercapnia results in rapid fetal acidemia, increases in intracranial pressure, and a rightward shift of the oxyhemoglobin dissociation curve.

DIAGNOSTIC IMAGING OF THE PREGNANT WOMAN

Use of ionizing radiation is a major concern for most clinicians evaluating a pregnant patient. Risks that need to be considered when ordering an imaging study involving the use of ionizing radiation are the risk of malignancy and the risk of teratogenicity. A general principle in ordering diagnostic imaging should be to balance the accurate medical care of the mother with potential risks of radiation exposure to the fetus and the mother.

The risk of oncogenicity follows a stochastic (non-threshold) effect, suggesting that the risk of malignancy may occur even at low levels of exposure. This risk is not evenly distributed, as recent data suggest a lower risk of cancer when exposure occurs in utero compared with exposure in childhood.[29] The risk of teratogenicity, however, does follow a threshold effect. Based on animal and human studies of radiation exposure, a threshold has been determined for congenital malformations and miscarriage. For diagnostic tests resulting in a fetal exposure of 10 cGy or less, the risk of radiation to the embryo is very small. More conservative recommendations aim for a maximum exposure of 5 cGy. With the exception of computed tomography venography, radiation exposure from imaging procedures used for the workup of a patient with a suspected or diagnosed respiratory disorder does not exceed 5 cGy (Table 96-2).[30] As the risk of radiation below 10 cGy is miniscule, medical care of the mother takes priority over the risks of diagnostic radiation exposure to the fetus, especially when imaging is necessary for appropriate management of lung disease.[31]

Another consideration in diagnostic imaging studies includes the use of contrast agents. Iodinated contrast media are small molecules that are known to cross the placenta and carry a potential risk of thyroid dysfunction in utero. However, in a study of 350 women who received iodinated contrast in pregnancy, none of the infants had any significant thyroid dysfunction.[32] The study was, however, performed in the northeast United States, an area where iodine deficiency is rare. Use of iodinated contrast is, therefore, certainly justifiable. However, iodine reserve, timing of the study in pregnancy, and maternal renal function should be considered.

TABLE 96-2 Radiation Exposure to the Fetus Associated with Various Diagnostic Procedures

Diagnostic Test	Radiation Dose (cGy)
Chest radiography	<0.001
Ventilation scintigraphy[262]	0.028–0.051[a]
Perfusion scintigraphy[262] (half dose)	0.014–0.025
CT pulmonary angiography[263]	0.0003–0.0131
Conventional pulmonary angiography	<0.05 via brachial route; 0.2–0.3 via femoral route
CT venography	>5
Conventional venography	0.6
Chest Fluoroscopy[31]	<0.01 cGy/min
IR abdominal fluoroscopy[31]	0.6 cGy/min
PET[31]	0.8–1.6

CT, computed tomography; PET, positron emission tomography.

Gadolinium is usually used with nonionizing-radiation imaging studies (i.e., MRI) and is known to cross the placenta.[33] The effect of gadolinium on the growing fetus is unknown, as human safety data are very limited. Hence, use of gadolinium should be reserved for cases where benefit outweighs the potential unknown risk of gadolinium exposure.

Diagnostic studies involving radionuclides, such as a pulmonary ventilation/perfusion scan, expose the fetus to radiation differently than external radiation. Given that radionuclides are excreted by the kidneys and may pool in the bladder, continuous exposure to the fetus may occur after the study has been completed.

INTERVENTIONAL PROCEDURES IN PREGNANCY

Indications for interventional pulmonary procedures in pregnancy are no different than in the nonpregnant population. As with any intervention, the risk of the intervention should be weighed against the risk of an inappropriate diagnosis or untreated disease. For example, the risk of bronchoscopy in pregnancy may be related to the procedure itself, as well as to the sedatives used during the procedure. Medication effects may be even more pronounced in the pregnant patient, given the altered physiology of pregnancy, including drug distribution, response to sedatives, and decreased airway patency.

In pregnant women, an upper airway evaluation should be performed prior to every procedure, given the higher risk of intubation failure in pregnancy. Risk of aspiration also may be increased because of a decrease in lower esophageal pressures and increase in intra-abdominal pressures. To minimize the risk of hypotension and hemodynamic instability during procedures performed in the second half of pregnancy, patients should be positioned supine with a left tilt to relieve the compression of the inferior vena cava by the gravid uterus.

Given the risk of hypoxemia with bronchoscopy,[34] especially when bronchoalveolar lavage is performed,[35] oxygenation should be monitored routinely and supplemental oxygen administered as needed to keep oxygen saturation above 95%. Fetal monitoring should be discussed with the obstetric team; however, in general, fetal monitoring prior to 28 weeks of gestation can be unreliable and difficult to interpret, while monitoring prior to 24 weeks is likely unnecessary.[36] Since pregnant women may develop hypercapnia and hypoxemia more quickly than nonpregnant women,[37] smaller doses of sedation might be considered. Midazolam, meperidine, fentanyl, and lidocaine have not been reported to be associated with congenital malformations.[33]

Fluoroscopy during bronchoscopy can be used in pregnancy, given the low dose of radiation associated with its use (Table 96-2)[30] and the fact that the fetus is not in the radiation field. A discussion with the institution's medical physicist can help keep radiation exposure to a minimum. Pleural procedures also can be performed in pregnancy, but providers should keep in mind the potential 4- to 5-cm cranial displacement of the diaphragm during pregnancy. Ultrasound guidance may help minimize risks of the procedure.

PHARMACOTHERAPY CONSIDERATIONS IN THE PREGNANT PATIENT

Over-the-counter drugs and prescription medications are frequently used during pregnancy. Although a number of drugs have been clearly shown to be either teratogenic or safe in pregnancy, insufficient safety data exist for most. Most data on safety for a given drug in pregnancy are based on animal studies, case reports or series, case-control studies, or pregnancy registries. Prospective studies evaluating safety are scarce. Integral to the discussion is the patient's understanding of the limitations of the available data and the intricacies of pharmacotherapy in pregnancy.

In 2015 the U.S. Food and Drug Administration (FDA) shifted away from a designated letter classification for drugs (A, B, C, D, X) to narrative sections about drug effects on pregnancy, lactation, and fertility. Even so, these descriptions still have shortcomings, especially when drug safety data are scarce, and initiation of any medication in a pregnant woman requires a thorough discussion between the patient and the provider about risks of treatment with the drug, and the risk of untreated disease. Often the data surrounding risk of a drug are based on animal studies alone in lieu of clinical trials in humans, and thus caution should be used when extrapolating and interpreting data. Breastfeeding is associated with significant benefits to newborns, such as a lower risk of obesity, diabetes, and cardiovascular disease, among others,[38–40] and drug passage into breast milk is an important consideration. Table 96-3 summarizes data on commonly used drugs in pregnancy and lactation. Reprotox.org is an excellent source of updated information on drug safety data during pregnancy and lactation. Medications and Mothers Milk is another source of information on medication use and breastfeeding.

SMOKING DURING PREGNANCY

Estimates are that 22% of women of reproductive age in the United States smoke. Data from Europe and the United States show that 10.7% to 13.1% of fetuses are exposed to maternal smoking. Although about half of women smokers quit during pregnancy, many women start smoking again after delivery.

Smoking is associated with adverse fetal outcomes. Various mechanisms may be responsible. Placentas from smokers have reduced capillary volume and increased thickness of villous membranes.[41–43] Carboxyhemoglobin is cleared slowly from the fetal circulation and competes with fetal oxyhemoglobin. Amniocytes from smokers have an increased incidence of structural chromosomal abnormalities compared with nonsmokers.[44] In addition, nicotine promotes platelet activation, impairs estrogen synthesis, and can directly impair lung development due to interaction with nicotinic acetylcholine receptors.

Smoking is associated with placental abnormalities, premature rupture of membranes, decreased thyroid function, psychiatric illness, reduced fertility, and conception delay,[45–49] as well as decreased production of milk volume, and lower rates and shorter duration of breastfeeding.[50] Prospective[51] and retrospective[52] studies confirm an association of fetal growth restriction with smoking during pregnancy, even in the first trimester.[53] Both active and secondhand smoke exposures are associated with increased risk of first trimester pregnancy loss.[54] Smoking in pregnancy increases healthcare costs for both mothers and neonates, even after adjusting for the protective effect against preeclampsia.

Babies born to pregnant smokers are also at risk for preterm birth.[55] The association of smoking with a risk of congenital anomalies[56] is a complex issue and may be closely related to maternal genotype. Maternal smoking during pregnancy is also associated with adverse cognitive and behavioral outcomes in the offspring, such as low scholastic achievement, attention deficit and hyperactivity disorder, conduct disorder, regular smoking,[57] wheezing, and asthma.[58] Childhood exposure to secondhand smoke is associated with upper and lower respiratory tract infections, ear infections, sudden infant death syndrome (SIDS), and asthma.[59–61]

Smoking cessation at any point during pregnancy is likely associated with some benefit.[62] According to recent economic model analyses, smoking cessation in randomized trials in pregnancy was also likely to result in cost savings.[63] Pregnancy offers a unique opportunity for smoking cessation, given the mother's motivation for fetal well-being and her frequent contact with healthcare providers. Women should be screened for secondhand smoking exposure, as well as potential abuse of other substances and comorbid psychiatric illness. Women should also be followed for smoking abstinence into the postpartum period, given the high rate of smoking relapse.

TABLE 96-3 Drug Safety in Pregnancy and Lactation[33]

	Pregnancy	Lactation
Ambrisentan	Ambrisentan is expected to be teratogenic, given its mechanism of action and known teratogenicity in animal studies. No human data.	Infant risk cannot be ruled out. It is not known whether ambrisentan is excreted into human milk. **AAP:** Not reviewed
Amoxicillin/ clavulanate	Amoxicillin/clavulanate is acceptable for use during pregnancy but use peri-delivery may increase the risk of necrotizing enterocolitis in neonates. Penicillins are generally considered to be safe for use in nonallergic patients during pregnancy.	No harmful effects have been reported. **AAP:** Maternal Medication Usually Compatible with breastfeeding **Lactation Risk Category:** L1
Azathioprine	Based on human case series, azathioprine is unlikely to increase the risk of congenital anomalies.	Caution is recommended. Monitor the infant closely for signs of immunosuppression, leukopenia, thrombocytopenia, hepatotoxicity, pancreatitis, and other symptoms of 6-mercaptopurine exposure. The risks to the infant are probably low. Recent long-term data suggest that the rate of infections in treated groups is no different from nontreated controls. **Lactation Risk Category:** L3
Benralizumab	Benralizumab is a humanized monoclonal antibody (IgG) that may be used in pregnancy in uncontrolled asthma if other treatments fail. However, IgG molecules cross the placenta in the second trimester. Pregnancy and fetal outcome studies are currently underway.	It is not known if benralizumab is excreted in breast milk but is likely present.
Beta agonists	β2 agonists are not associated with congenital malformations (GINA 2020). Albuterol is listed as preferred beta agonist in 2004 NIH report on treatment of asthma in pregnancy. High doses (32 mg/d) of oral albuterol appeared to prolong gestation in a population of 132 pregnancies.[264] Various birth defects were described in association with albuterol and may have been due to chance.	Safe to use in breastfeeding mothers. Use via inhalation is recommended. **AAP:** Not reviewed **Lactation Risk Category:** L1
	Salmeterol is not expected to increase the risk of congenital malformations. Formoterol is not expected to increase the risk of malformations, but human data are inadequate.	Safe to use in breastfeeding women. Levels in breast milk very low to undetectable. **AAP:** Not reviewed **Lactation Risk Category:** L2
Bosentan	Bosentan is believed by its manufacturer to increase the risk of major congenital anomalies in humans, based on rodent studies and the known mechanism of action of the medication.	No data are available on the transfer into human milk, but based on its structure, bosentan levels in the milk compartment would probably be very low. However given 50% oral bioavailability and high incidence of liver toxicity, great caution is recommended with this product in breastfeeding mothers until we have published milk levels. **Pediatric Concerns:** No data are available. May be dosed down to children weighing at least 22 lb. **Lactation Risk Category:** L4
Budesonide inhaler	No association with congenital birth defects. Children exposed to inhaled steroids are more likely to develop endocrine, metabolic, and nutritional disorders.	Unlikely clinically relevant concentrations of budesonide reach breast milk. **Lactation Risk Category:** L1
Bupropion (Wellbutrin)	Bupropion has not been associated with an increased risk of congenital defects; however, pregnancy registry data have called attention to a possible weak association with congenital heart defects (not confirmed in other studies).	Bupropion may, in some women, suppress milk production. Some caution is recommended concerning changes to milk supply. **AAP:** Drugs whose effect on nursing infants is unknown but may be of concern
Cephalosporins	Cephalosporins may cross into the fetal circulation in small amounts, but teratogenicity has not been attributed to these agents.	As a highly protein-bound group, the cephalosporins do not pose a significant risk to the nursing infant.
Cyclophosphamide	Experimental animal studies and human case reports have shown adverse effects on fertility and embryo development. Birth defects have been demonstrated in all animal species tested.	Cyclophosphamide is excreted into human milk. It has been classified as a drug that may interfere with cellular metabolism of a nursing infant by the American Academy of Pediatrics.

(continued)

TABLE 96-3 Drug Safety in Pregnancy and Lactation[33] *(Continued)*

	Pregnancy	Lactation
Cyclosporin	Experimental animal studies do not predict an increase in congenital anomalies after pregnancy exposure to cyclosporins. A limited number of human cases are also reassuring, although premature birth and low birth weight are observed. Solid organ transplant recipients are recommended to stay on the drug, but alternatives are recommended for treatment of psoriasis and lupus nephritis if possible. Formulations may contain alcohol.	Cytotoxic drug that may interfere with cellular metabolism of the nursing infant. Close observation of the infant, including monitoring of the infants' plasma levels, is required. There should be strong consideration to discontinue the drug if breastfeeding. **AAP:** Possible immune suppression; unknown effect on growth or association with carcinogenesis **Lactation Risk Category:** L3
Dexamethasone	Glucocorticoid use in pregnancy can increase the risk of cleft palate and impaired fetal growth, but small epidemiologic studies did not demonstrate this association with dexamethasone specifically. Extended courses for pregnant women are best avoided, but the benefit may outweigh the risk.	There are no specific studies on dexamethasone, but overall corticosteroids enter human milk in small amounts. Mothers may wait 4 h after a dose to nurse. **AAP:** Prednisone/prednisolone compatible with breastfeeding
Elexacaftor/ tezacaftor/ivacaftor (Trikafta)	Based on animal studies, Trikafta is not likely to cause congenital anomalies. There is transfer of Trikafta to the fetus via fetal circulation, but anecdotal cases of pregnancy among women on Trikafta have not shown serious adverse outcomes. The European Respiratory Society and the Thoracic Society of Australia and New Zealand consider Trikafta to be "probably safe" in pregnancy.	The European Respiratory Society and the Thoracic Society of Australia and New Zealand consider Trikafta to be "probably safe" in lactation. Animal models demonstrate excretion of Trikafta in breast milk.
Epoprostenol sodium	It is unknown if epoprostenol shares any of the abortifacient properties of other prostaglandins, but the manufacturer reports no adverse events noted based on available data (limited). Overall, use should be avoided if possible.	Unknown **AAP:** Not reviewed **Lactation Risk Category:** L3
Gentamicin	Ototoxicity and nephrotoxicity in the fetus are theoretical possibilities that have not been confirmed clinically. This agent is known to cross the human placenta at term, but its use is likely justifiable in certain conditions.	**AAP:** Compatible with breastfeeding **Lactation Risk Category:** L2
Iloprost (Ventavis)	No epidemiologic studies of congenital anomalies among infants born to women who were treated with iloprost during pregnancy have been reported. Iloprost has been shown to be teratogenic in rats due to its systemic circulatory effects.	It is not known whether iloprost appears in milk. Increased mortality of nursed rat pups was reported, and the manufacturer recommends discontinuing nursing in women being treated with iloprost.
Ipratropium bromide	Based on animal studies, ipratropium is not expected to increase the risk of congenital malformations.	Transfer into breast milk in exceedingly small and clinically insignificant levels. **Lactation Risk Category:** L2
Leflunomide	Experimental animal studies demonstrated interference with embryo development and viability at high doses. Product labeling contains a warning against the use of this drug in pregnancy based on an 8% rate of congenital anomalies in human pregnancies.	Experimental studies showed >90% decrease in postnatal pup survival after exposure to leflunomide during late pregnancy and lactation; hence labeling states that this medication should not be used in nursing mothers.
Linezolid	Linezolid does not cause congenital malformations in mice and rats, even at high doses. There are no human data.	Minimal human data available. Linezolid is transferred to breast milk with a likely maximal dose of 2 mg/kg daily (with maximal dose for infants being 30 mg/kg daily). **Lactation Risk Category:** L3
Macrolide antibiotics	*Erythromycin* use during pregnancy is unlikely to increase teratogenic risk to the fetus. *Clarithromycin* may increase the risk of adverse pregnancy outcomes. In a series of observational studies, *azithromycin* did not cause an increased rate of congenital anomalies when used during pregnancy.	Pyloric stenosis has been associated with the use of erythromycin in the early postpartum period. **AAP:** Usually Compatible with breastfeeding **Lactation Risk Category:** L3
Mepolizumab	There are no human data on mepolizumab in pregnant women; however, animal studies did not show adverse fetal effects.	There are limited data on the presence of mepolizumab in human breast milk; however, it was detected in breast milk after administering to pregnant monkeys.

TABLE 96-3 Drug Safety in Pregnancy and Lactation[33] *(Continued)*

	Pregnancy	Lactation
Methotrexate	Methotrexate increases the incidence of congenital anomalies in experimental animals and appears to do so in humans as well. Methotrexate is used clinically as an abortifacient[265–267] and in the treatment of ectopic pregnancy. One study indicates a higher risk of fetal malformation in mothers who received methotrexate months prior to becoming pregnant.[268] Therefore, pregnancy should be delayed for at least 3 months following therapy if either partner is receiving methotrexate.	Methotrexate is believed to be retained in human tissues (particularly neonatal gastrointestinal cells and ovarian cells) for long periods (months). It is apparent that the concentration of methotrexate in human milk is minimal, although due to the toxicity of this agent, it is probably wise to pump and discard the mother's milk for a minimum of 2–4 d. **AAP:** Possible immune suppression; unknown effect on growth or association with carcinogenesis; neutropenia. **Lactation Risk Category:** L3
Montelukast	Montelukast is unlikely to increase risk of congenital abnormalities; however, there is currently an FDA warning related to reports of limb reduction defects. In total there are *six* cases reported of limb reduction defects, but causality is unknown.	The nursing infant is exposed to approximately 0.68% of the maternal dose, which is well below the therapeutic dose.
Mycophenolate mofetil	Mycophenolate mofetil is associated with an increased risk of miscarriage and congenital malformations. A pregnancy registry has been established by the manufacturer.	Mycophenolate is excreted in milk of rats. Human data are scarce. Product labeling recommends avoiding using the drug during lactation.
Nicotine replacement	Smoking cessation is strongly recommended in pregnancy. However, recommendations regarding nicotine replacement therapy are less clear due to known fetal toxicity of nicotine. Nicotine therapy may decrease fetal growth similarly to smoking. Nicotine metabolism is higher in pregnancy possibly requiring higher doses..	Nicotine is secreted into human milk. Use of replacement products is compatible with breastfeeding. **AAP:** Not reviewed **Lactation Risk Category:** L2
Omalizumab	Data in monkeys are reassuring, but currently, there are no human data. Pregnancy registry exists.	Omalizumab may be secreted into human milk but levels likely very low. Oral bioavailability extremely low. **AAP:** Not reviewed **Lactation Risk Category:** L3
Penicillin	Penicillins are not believed to increase adverse pregnancy outcome. Penicillins accumulate in amniotic fluid during maternal ingestion. No adverse fetal effects have been associated with this process.	Usually compatible with breastfeeding. Penicillins are excreted into human milk in small amounts with possible alterations in bowel flora and potential risk of allergic sensitization in the infant.
Penicillamine	Experimental animal studies and some case reports suggest an association with congenital connective tissue disorders including lax skin and inguinal hernia.	It is possible that copper and zinc concentrations may be reduced in breast milk of mothers taking penicillamine and possible need for supplementation. Some case reports and case series describe no complications in breastfeeding infants of mothers taking penicillamine.
Prednisone	Prednisone and other glucocorticoids are associated with fetal growth impairment in humans. Prednisone is metabolized by the placenta to a large extent, and minimal doses reach the fetus. Other steroids, such as betamethasone, are less well metabolized by the placenta and are used to enhance lung maturity in pregnancies expected to end preterm. These medications increase oral clefting in experimental animals and may do so in humans in early pregnancy exposure.	Small amounts of most corticosteroids are secreted into breast milk. With prolonged high-dose therapy, the infant should be closely monitored for growth and development. **AAP:** Usually Compatible with breastfeeding **Lactation Risk Category:** L2
Quinolones	Quinolones are avoided during pregnancy due to cartilage toxicity demonstrated in experimental animals. Human data are not supportive.	Quinolones are secreted in milk. Infants should be observed for changes in gut flora, *Candida* overgrowth, or diarrhea. The use of quinolones in the pediatric population is increasing due to minimal evidence of cartilage toxicity. **AAP:** Not reviewed **Lactation Risk Category:** L2
Remdesivir	Based on animal studies, remdesivir is not likely to cause congenital anomalies.	There are no human data on remdesivir and lactation. In animal studies, there is transfer of remdesivir and its metabolites to pups but no adverse effects.
Reslizumab	Based on animal studies, reslizumab is not likely to cause congenital anomalies. Human data are lacking. IgG molecules cross the placenta in the second trimester.	Reslizumab was present in mouse breast milk at 5%–7% of maternal concentrations with no adverse effects. There are no human data.

(continued)

TABLE 96-3 Drug Safety in Pregnancy and Lactation[33] *(Continued)*

	Pregnancy	Lactation
Riociguat	Riociguat was consistently shown to have teratogenic effects when administered to animals. Pregnancy test should be performed prior to initiating therapy and monthly while on therapy in reproductive-age women.	It is not known whether the drug transfers via breast milk in human but appears to do so in rats. Given the potential for serious adverse reactions in nursing infants, nursing should be discontinued in women on riociguat.
Rituximab	In animal studies, rituximab did not interfere with embryo development in monkeys. There was no evidence of an increase in adverse outcomes in humans in a pregnancy registry. Rituximab is present in cord blood demonstrating transplacental transfer of the agent near term, and depletion of B cells was demonstrated in an exposed neonate.	Rituximab has been demonstrated in monkey and human milk. Product labeling recommends that breastfeeding be avoided by breastfeeding women.
Sildenafil	Based on experimental animal studies, sildenafil does not appear to increase the risk of congenital malformations in exposed pregnancies.	There are insufficient data to determine the safety of sildenafil in human lactation.
Tacrolimus	Based on experimental animal studies and human case reports, tacrolimus is not expected to increase the risk of congenital anomalies. Hypertension, prematurity, and neonatal hyperkalemia have been suggested by case reports as possible adverse effects.	According to the manufacturer, tacrolimus is excreted in breast milk and should be avoided during lactation. However, studies in lactating mothers suggest the exclusively breastfed infant would receive less than 0.2% of the pediatric dosage for organ transplant rejection. **AAP:** Not reviewed **Lactation Risk Category:** L3
Tocilizumab	Based on animal studies, tocilizumab is not expected to cause congenital anomalies; however, embryofetal death was reported in monkeys. Human case series are limited, and there is an ongoing registry for pregnant mothers receiving tocilizumab.	Limited human data implies that absorption of tocilizumab by the infant via breast milk is unlikely. Small observational studies did not find adverse effects on nursing infants.
Treprostinil	Based on experimental animal studies with subcutaneous treprostinil, adverse effects in pregnancy are not anticipated. Human data and data on drug inhalation are lacking.	Manufacturer states that no reports describing the use of treprostinil during human lactation are available and the effects on the nursing infant from exposure to the drug in milk are unknown.
Vancomycin	Based on experimental animal studies, vancomycin is not expected to increase the risk of congenital malformations. Theoretical concern exists regarding ototoxicity and nephrotoxicity, but supportive evidence in humans is not available.	Only low levels are secreted into human milk. Its poor absorption from the infant's gastrointestinal tract would limit its systemic absorption. Low levels in infants could provide alterations of gastrointestinal flora. **AAP:** Not reviewed **Lactation Risk Category:** L1
Varenicline (Chantix)	Based on experimental animal studies, use of varenicline during pregnancy is not expected to increase the risk of congenital malformations. Human data are not available.	There have been no studies performed on the transfer of varenicline into human milk. **Lactation Risk Category:** L4

Various nonpharmacologic interventions for smoking cessation have been examined. Providing an incentive to encourage smoking cessation has been shown to be an effective strategy in some studies; however, the ethical framework and implications of such strategies is being questioned.[64]

Pharmacotherapy for smoking cessation in pregnancy has limited data regarding efficacy and safety. The United States Preventive Services Task Force states that the use of pharmaceuticals has not been sufficiently evaluated to determine their safety or efficacy in pregnancy.[65] Data on nicotine replacement therapy show conflicting evidence with regard to safety.[66,67] Many trials have been halted in the United States because of either adverse effects or failure to demonstrate effectiveness.[68,69] The Danish National Birth Cohort of 72,761 women showed no significant association between type or duration of nicotine product use and birth weight.[70] A recent meta-analysis demonstrated that current evidence from randomized and nonrandomized studies do not provide clear evidence of whether nicotine replacement was associated with fetal harm.[71] Overall, the risk from various chemicals in cigarette smoke likely outweighs the small risk of possible weight reduction from nicotine pharmaceuticals.

Although animal data on the safety of use of varenicline in pregnancy are available, human data are lacking. Varenicline is likely transferred through breast milk; however, data are not available. Bupropion has not been associated with an increase in congenital defects in experimental animal studies, although pregnancy registry data for bupropion calls attention to a possible association with congenital heart defects.[72] Although bupropion is passed to the fetus in breast milk, based on measurement of infant plasma levels, the dose transmitted is unlikely to be clinically significant. A recent meta-analysis examining the effect of varenicline and bupropion use in smoking cessation in pregnancy showed no major impact on congenital abnormalities, birthweight, or premature birth.[73]

MANAGEMENT OF ASTHMA DURING PREGNANCY

Asthma is the most common respiratory disease of pregnancy, affecting 2% to 13% of pregnancies worldwide.[74,75] Asthma may improve, worsen, or remain unchanged in pregnancy.[76] Predictors of disease course include prepregnancy asthma severity, race, presence of obesity, compliance with medication use, and patient difficulties in accessing antenatal care. Factors contributing to modifications of disease severity include a number of pregnancy-associated conditions: higher prevalence of gastroesophageal reflux disease,[77] nasal congestion,[78] alterations in immunity, and hormonal factors.[79] The rate of asthma exacerbations is increased between 17 and 32 weeks of gestation.[76,80] Improvement in the last few weeks of pregnancy may be related to significantly higher levels of cortisol, an anti-inflammatory hormone, compared with preconception levels.

Poorly controlled asthma may negatively impact some maternal and fetal outcomes. In a large study, asthmatic women were more likely to have pregnancies complicated by miscarriage, antepartum and postpartum hemorrhage, anemia, or depression.[81] In a retrospective cohort study performed in 12 clinical centers in the United States, asthmatics experienced increased risk of preeclampsia; gestational diabetes; preterm births, including spontaneous preterm birth; and induced preterm birth.[82] A systematic review of nine studies has shown an increased risk of preterm birth, small for gestational age, and low birthweight if the mother has asthma.[83] Babies born to asthmatic mothers may be more likely to have congenital anomalies.[84,85]

Since pregnancy does not affect air flow rates, reductions in peak expiratory flow rate (PEFR) should prompt quick medical evaluation. In a multi-institutional prospective study, lower forced expiratory volume in one second (FEV_1), but not symptom control, was associated with adverse perinatal outcomes.[86] These data may be related to the fact that, given the high prevalence of physiologic dyspnea in pregnancy, symptom interpretation by both providers and patients may be difficult without objective measures; hence, the need for close physiologic monitoring is apparent.

Most medications used to treat asthma are safe for use in pregnancy **(Table 96-3)**. An important message to patients is that good asthma control is the main goal, and the risk of medication use is lower than the risk of adverse outcomes from untreated or poorly treated disease. Recent evidence from a double-blind, randomized, controlled trial suggests that pregnant women managed according to a validated treatment algorithm based on measurements of exhaled nitric oxide (FeNO) had fewer exacerbations compared with those treated according to a symptom-based approach.[87] Despite an updated FDA warning on montelukast being possibly associated with congenital anomalies, the drug may need to be used in women whose asthma cannot be controlled without a leukotriene receptor antagonist. Newer biologics have scarce fetal safety data, but as IgG molecules they are expected to cross the placenta in the second trimester. Details regarding their appropriate dosing, efficacy, and impact on childhood vaccination have yet to be investigated.

Patients with more severe disease, or those who suffer an exacerbation close to term, require a detailed labor and delivery plan. Stress dosing with corticosteroids during labor should be considered in patients who have been on prolonged courses of systemic steroids during the pregnancy. Patients with active symptoms or more severe asthma may benefit from regional anesthesia aimed at reducing minute ventilation and oxygen consumption and preventing hyperinflation. If general anesthesia is considered, ketamine and halogenated anesthetics are preferred. Oxytocin and prostaglandin E2 are safe to use. However, other prostaglandins used for induction of labor, morphine, and meperidine should be avoided, since they may cause worsening bronchospasm.

CYSTIC FIBROSIS AND PREGNANCY

Cystic fibrosis (CF) impacts fertility in both men and women. Women with CF have various reproductive system abnormalities. Since the CF transmembrane conductance regulator (CFTR) is present in reproductive organs, cervical mucus is thicker and more tenacious, leading to obstruction of the cervical os and impaired sperm penetration. Despite these changes, fertility occurs in women with CF, and affected women should be counseled regarding contraception. Women with higher body weight and higher FEV_1 are more likely to desire and achieve pregnancy[88] and with newer generations of protein modulator therapies, more women are likely to attempt pregnancy.[89] Genetic screening of both mother and father can help assess the risk of CF in the offspring. Preimplantation genetic diagnosis can be performed during assisted reproduction and may help detect embryos affected by the disorder.

In two series reporting on 72 and 90 pregnancies in patients with CF, the need for intravenous antibiotic therapy was 65% to 77%, and higher rates of hospitalization compared to nonpregnant patients were reported.[90,91] FEV_1 may decline during pregnancy in CF, and then improve in some patients following delivery.[92] However, in larger case-controlled series, the FEV_1 decline appears similar to that experienced by nonpregnant patients with CF.[90,93] Reduced FEV_1 appears to be a predictor of adverse outcomes in pregnancy in CF,[91] including early mortality following delivery. Other predictors of decreased survival include maternal colonization with *Burkholderia cepacia* and pancreatic insufficiency.

Increased energy expenditure in pregnancy makes weight gain more challenging. Glucose intolerance and gestational diabetes occur as a result of decreased insulin production, impaired insulin sensitivity, and increased hepatic glucose production.[93,94] Multiple studies have shown an increased risk of preterm delivery,[90,95] possibly related to altered lung function. The risks of fetal demise and birth defects are likely similar to controls.[90,91,93]

Treatment of CF requires multiple chronic therapies such as antibiotics, inhaled medicines and CFTR modulators. Azithromycin, penicillins, and cephalosporins are safe to use in pregnancy. In animal studies, use of fluoroquinolones may be associated with increased risk of abnormal cartilage development; similar effects have not been observed in human studies.[96] Use of tetracyclines is hard to justify in pregnancy, since they result in tooth and bone discoloration. Rifamycins are associated with an increased risk of fetal damage and bleeding in both mother and neonate.[97] Dornase alfa use has been described in pregnancy,[98] but safety data are limited. Safety data on use of pancreatic enzyme replacement therapy also are limited,[99,100] but use is likely justifiable. Vitamin replacement can be used in pregnancy; however, vitamin A supplementation should not exceed 10,000 U daily because of teratogenic effects. Although sulfonylureas are likely safe in pregnancy, they are associated with an increased risk of fetal hypoglycemia. Insulin is the preferred glucose-lowering drug. Though the introduction of CFTR modulators has significantly impacted the outcomes of patients with CF, data on these therapies in pregnancy remain limited and more data are needed on the impact of these drugs on reproduction and contraceptives, as well as their fetal safety. Reports of the use of ivacaftor, alone, or in combination with tezacaftor or lumacaftor, did not show an association with congenital anomalies, but due to nonuniform reporting and variable exposure to the drug, these data do not establish safety.[33] The European Respiratory Society and the Thoracic Society of Australia and New Zealand have deemed the drugs as “probably safe” for use during pregnancy and lactation.[101]

Vaginal delivery is the expected mode of delivery in CF unless other indications for cesarean section exist. Epidural anesthesia may help with minimizing minute ventilation and oxygen consumption in patients with reduced lung function. Breastfeeding may not be advisable for women with poor nutritional status.

PNEUMONIA IN THE PREGNANT WOMAN

Sepsis is among the leading causes of maternal death in the world, especially in developing regions. Pneumonia in particular is one of the most common causes of non-obstetric mortality in the United States.[102,103] In addition, in a national study in Colombia examining causes for respiratory failure in pregnancy as a cause of maternal deaths between 1998 and 2009, pneumonia was the most common cause.[104] The risk of pneumonia is increased in pregnant women with comorbid conditions, such as asthma, anemia, HIV infection, and tobacco or substance abuse.[105] Pregnant women may be more susceptible than nonpregnant women to contracting viral infections, and they may have more severe disease than those who are not pregnant. Immune alterations associated with normal pregnancy may impair the response to infection and increase the risk of certain infections.

Preterm delivery appears to be the most common complication associated with pneumonia. Other potential complications include low birth weight, intrauterine growth restriction, a fetus that is small for gestational age, placental abruption, preeclampsia or eclampsia, and low Apgar scores.[106–108] Varicella infection increases morbidity and mortality in pregnancy and is associated with congenital abnormalities and poor fetal outcomes especially in the first trimester. Congenital varicella syndrome is associated with high mortality in the first 30 days of life and severe impairment related to neurologic, cardiac, gastrointestinal, and developmental delays in survivors.

In the pregnant patient with pneumonia, antibiotic therapy should be initiated empirically while awaiting confirmatory tests that may aid in narrowing the antimicrobial coverage. During influenza season, antivirals (usually oseltamivir) should be started empirically. Extensive use of oseltamivir during the 2009 H1N1 epidemic was thought not to be associated with any adverse fetal effects. Intravenous acyclovir or valacyclovir should be used in patients with a suspicion of varicella pneumonia; those suspected of varicella infection should be admitted for observation.

Case series of pregnant women with SARS-CoV-2 disease (COVID-19) have shown increased risk of preterm birth[109] and more severe maternal disease compared with nonpregnant patients. Severe maternal morbidity also may occur.[110] While vertical transmission of SARS-CoV-2 is possible, it is uncommon. The low level of vertical transmission may be explained by low levels of maternal viremia, as well as reduced expression of the angiotensin-converting enzyme 2 receptor and the serine transmembrane protease 2 in the placenta.[111,112] Antibodies formed in response to the COVID-19 infection do not appear to cross the placenta or provide immunity to the neonate; however, it is unclear whether the same is expected following vaccination.[111] Preliminary studies do not show harm in vaccinated patients who are pregnant.[113]

Women with COVID-19 may continue to breastfeed their babies while wearing a mask, and available data suggest low risk of transmission with proper hygiene and masking methods.[114]

Remdesivir, the antiviral of choice in COVID-19, has been used in pregnant women. The FDA recommends its use after weighing the potential risks and benefits for mother and fetus. Animal studies have not shown any embryofetal harm when remdesivir is administered systemically at four times the recommended human dose. It is thought that remdesivir is likely present in breast milk at lower concentrations than maternal plasma.

The use of dexamethasone, which has been shown to be beneficial in COVID-19, should be used for severe hypoxic respiratory failure in pregnant women with COVID-19, although there is a risk of suppression of the fetal adrenal function.

According to the manufacturer,[115] there are insufficient data on the safety of bamlanivimab and etesevimab in pregnancy, alone or in combination, and the risk of untreated disease needs to be weighed against the unforeseen potential risk of the drug. There are also no data on the transfer of either monoclonal antibody into breast milk in either animals or humans. Data on the use of other COVID-19 therapy such as Tocilizumab and Baricitinib are emerging. Neither drug is expected to increase the risk of congenital malformations, and as with any medication, benefit of use should be weighed against the risk of severe disease in pregnancy. Pregnancy registries exist at mothertobaby.org/ongoing_studies.

Antibiotic use in the pregnant patient with CF has been discussed previously; Table 96-3 provides additional details. Although use of aminoglycosides or vancomycin theoretically may be associated with hearing and renal dysfunction in the fetus, in most circumstances where there is an indication for one or the other agent, its benefit likely outweighs its risk.

In pregnant women with acute respiratory failure from pneumonia or other causes, decisions regarding oxygenation and ventilation should be predicated on the previously discussed physiology. Airway intubation should be anticipated and performed by the most experienced personnel available, using advanced airway devices and readily accessible equipment, given the high risk of intubation failures in pregnant women.

TUBERCULOSIS: CLINICAL COURSE AND MANAGEMENT DURING PREGNANCY

Tuberculosis (TB) is an important infection of pregnant woman. In sub-Saharan Africa, TB is the third leading cause of maternal death, following sepsis and hypertensive disorders of pregnancy.[116] In the United States, a steady overall decline in the incidence of TB has been observed, but a rise in incidence has been seen in the 15- to 45-year-old age group. As a result, an increase in the prevalence of TB among pregnant women in certain communities, for example, New York City, has been reported.[117]

The risks of TB to the mother and unborn child include intrauterine growth restriction, prematurity, and an increased risk for both maternal and fetal mortality. Transmission of TB to the fetus also is well documented[118–120] and may occur through hematogenous spread, by contiguous spread from endometrial TB, or via aspiration of TB-infected amniotic fluid. If neonatal TB is suspected, placental and endometrial tissue can be examined at the time of delivery; however, a workup of suspected active maternal TB should never be delayed until delivery. The diagnosis of TB in pregnancy often requires a high level of suspicion since fatigue and malaise can be confused with symptoms of pregnancy.

Pulmonary TB is the most common form of TB in pregnancy, accounting for up to 85% of all cases. Consequently, a chest radiograph is essential in making the diagnosis. Although tuberculin skin testing (TST) has been considered the gold standard for screening during pregnancy,[111] recent studies demonstrate that both TST and QuantiFERON-TB detection rates may be impacted by pregnancy[110] and different cut-offs may need to be considered in this population.[121]

Treatment of latent TB infection (LTBI) in pregnancy may be delayed until the postpartum period in pregnant women at low risk for reactivation.[122] This recommendation is based on a study showing a higher risk of INH-induced hepatitis in pregnant women compared with nonconcurrent controls.[123] However, in the study noted, the risk of INH-induced fatal hepatitis in both the active treatment and the control group was quite low. Conversion to active TB infection in patients coinfected with HIV is significant; therefore, immediate treatment should be initiated in coinfected patients to avoid placing the neonate, mother, and community at risk.

Pregnancy was originally believed to worsen the course of TB infection, but this has been shown not to be the case. Active, untreated TB infection in a pregnant woman is more of a hazard than the treatment. When active TB is confirmed, treatment should not be delayed. Treatment is similar to that in the absence of pregnancy. First-line therapies for TB, including rifampin, INH, and ethambutol, have been shown to be safe in pregnancy and unassociated with human fetal malformations.[124,125] INH does carry a risk of acute hepatitis, especially if the patient is treated concomitantly with rifampin. Pyrazinamide is less well studied. Although the World Health Organization (WHO) and the International Union Against Tuberculosis and Lung Disease note that the use of pyrazinamide is justifiable in pregnancy, the Centers for Disease Control and Prevention (CDC) does not recommend it in pregnancy. When drug resistance is suspected, addition of pyrazinamide may be needed. Second-line agents are considered more toxic than first-line agents, and clinical experience to guide their use and safety is lacking. Streptomycin should be avoided because of its fetal ototoxicity, while amikacin and kanamycin carry known fetal nephrotoxicity. Para-aminosalicylic acid (PAS) has been used with INH in the past, and there has been no evidence of teratogenicity among babies whose mothers received the drug.[126–128]

Breastfeeding should not be discouraged in women being treated for TB, unless the mother is thought to be infectious. Since anti-TB drugs are secreted in small concentrations in breast milk, caution should be exercised when breastfeeding newborns that are also being treated for TB, since that may increase the risk of drug toxicity. Transmission of mycobacteria via breast milk is, however, quite unlikely, except for rare cases of TB mastitis.

VENOUS THROMBOEMBOLISM: DIAGNOSIS AND MANAGEMENT DURING PREGNANCY

Diagnostic and management approaches for thromboembolic disease, including pulmonary embolism (PE), in the pregnant woman merit special considerations.

Diagnosis of Venous Thromboembolism and Pulmonary Embolism

Venous thromboembolism (VTE) is one of the leading causes of maternal mortality in the developed world. As such, when suspicion for disease is high, early implementation of therapeutic anticoagulation is important. In pregnancy, the risk of VTE is as high as 7 to 10 times that of nonpregnant, age-matched controls.[129] The risk is disproportionately higher in the postpartum period, and 70% of all VTE events that happen in the postpartum period occur within the first 20 days after delivery.[130] In pregnancy, 70% to 85% of deep venous thromboses (DVTs) occur in the left leg.[131,132] This is thought to be due to compression of the left iliac vein by the right iliac artery and the gravid uterus. Isolated pelvic DVT is more prevalent in pregnancy compared with the nonpregnant population,[132,133] possibly suggesting a different pathogenesis for the disorder.

The increased risk of VTE during pregnancy is due to stasis, hypercoagulability, and vascular damage. Venous stasis in the lower extremity is secondary to the gravid uterus, as well as hormonally mediated venodilation.[134] Pregnancy is marked by many changes in the coagulation cascade, which lead to a hypercoagulable state.[135] Finally, vascular injury occurs with delivery, thereby augmenting risk in the postpartum period.

Existing clinical pretest probability tools are not validated in pregnancy, and their utility is limited by the physiologic changes of pregnancy.[136] D-Dimer performance characteristics are different in pregnant women, and its measurement in pregnancy without concomitant diagnostic imaging to exclude VTE is unreliable.[137,138] Data from the Diagnosis of PE in Pregnancy (DiPEP) decision analysis modeling showed that neither clinical features, decision rules, nor biomarkers were reliably predictive of pulmonary embolism. Emerging evidence suggests that the incorporation of D-dimers may be helpful in decreasing the need for computed tomography pulmonary angiography (CTPA) in pregnant women suspected of pulmonary embolism.[139] Other data showed more favorable outcomes,[140,141] although when tested in the DiPEP population they demonstrated poor negative predictive ability for PE.[142] Hence, current data remain limited due to sample bias, the number of protocol deviations, and power.[140,141] Use of D-dimers cannot yet be relied upon to safely exclude pulmonary embolism in pregnancy.

Testing for symptomatic DVT in pregnant and nonpregnant individuals is similar: compression ultrasonography (CUS) is the standard of care.[143] In pregnancy, the sensitivity of CUS may not be as high, given the high prevalence of isolated pelvic vein thrombosis in pregnant patients.[132] Absence of flow or need for increased pressure during CUS may be suggestive of pelvic vein thrombosis. However, the low sensitivity of CUS in detecting iliac thrombi may necessitate the use of other imaging studies, such as nonenhanced magnetic resonance venography.

In pregnant women suspected of PE who also have lower extremity symptoms, CUS is the recommended initial test in those who are hemodynamically stable. In women without lower extremity symptoms, American Thoracic Society/Society of Thoracic Radiology guidelines recommend a chest x-ray (CXR) as the next diagnostic step.[144] A CXR may provide an alternative diagnosis and also determine the utility of a perfusion scan. Using the proposed diagnostic algorithm, patients with a normal CXR are next evaluated with a ventilation–perfusion lung scan, whereas those who have an abnormal CXR undergo a multidetector computed tomography–pulmonary angiogram (MDCT-PA).[144] The main advantage of MDCT-PA over a ventilation–perfusion scan is that it provides an alternative diagnosis in 17% to 19% of pregnant women suspected of having a PE.[145] MDCT-PA may be technically limited in up to 20% of pregnant women[146] due to physiologic changes of pregnancy, including a higher plasma volume and heart rate, which affect vascular enhancement. These effects may be more pronounced in women with obesity and those with multiple gestations. Imaging protocol modifications may help reduce technical limitations of the technique.[147]

Management of Thromboembolic Disease in Pregnancy

Since the interval between diagnosis of PE and institution of therapeutic anticoagulation has been shown to be an independent predictor of death, early and appropriate treatment is essential. In pregnancy, prognostic assessment tools, such as brain (B-type) natriuretic peptide (BNP), or cardiac echocardiography for evaluation of right ventricular dysfunction, are not well validated. Furthermore, their interpretations are limited by the physiologic changes of pregnancy.[148–150] Additional work in deriving prognostic indictors for thromboembolic disease in pregnancy is needed.

Both unfractionated heparin (UFH) and low-molecular-weight heparin (LMWH) are safe during pregnancy, as they do not cross the placenta. However, LMWH is superior to UFH for all measured outcomes of VTE—risk of recurrent thrombosis, bleeding, and death.[151,152] Other advantages of LMWH over UFH include a lower risk of heparin-induced thrombocytopenia and thrombosis (HIT) and bone demineralization with subsequent fractures.[153–155]

UFH may still play a role in pregnancy, particularly around labor and delivery, given its shorter duration of action and easy reversibility. Given UFH's increased clearance and volume of distribution (and, therefore, bioavailability), its use in pregnancy should be monitored.[156] UFH administered intravenously is the treatment of choice for patients with acute renal failure or if urgent need for drug reversal may be required for delivery.

Dosing and monitoring of LMWH is controversial. The American College of Chest Physicians recommends adjusted dosing once or twice daily for enoxaparin,[157] while the American College of Obstetricians and Gynecologists recommends weight-adjusted dosing twice daily[158] and the Royal College of Obstetrics and Gynecology recommends weight-based dosing once or twice daily.[159] Twice-daily dosing is preferred by many experts, guided by anti-Xa levels obtained 3 to 6 h after a dose, especially in women with obesity. The goal for anti-Xa levels is 0.5 to 1.1 units/mL. LMWH does not appear to increase the risk of peripartum bleeding over UFH. The incidence of peripartum hemorrhage is approximately 0.9% to 1.8%, whereas the risk of antenatal hemorrhage and wound hematoma is less than 1%.[160] Although most available data were derived from the study of enoxaparin, tinzaparin likely has a similar side-effect profile.[161]

The duration of treatment for VTE in pregnancy is not well defined; consequently, recommendations for management are similar to those in the nonpregnant patient. Consensus suggests that therapy for VTE should extend for at least 6 weeks into the postpartum treatment, since this is a high-risk time for thromboembolism. The total duration beyond that is unclear, but a minimum of three months is probably warranted and should be based upon careful assessment of the risk of recurrence.[162,163]

Thrombolysis may be warranted in cases of massive PE among pregnant women. The main risk of thrombolysis in pregnancy is maternal bleeding, which is reported to occur in as many as 8.1% of patients treated; no cases of intracranial hemorrhage have been reported.[164] In one series on the use of thrombolytics in pregnancy, although no maternal bleeding was reported, the rate of fetal mortality was 8%.[165] Fetal complications may be related to thromboembolic disease severity, as well as the choice of thrombolytic agent. Alteplase (rt-TPA) does not cross the placenta and carries no risk for teratogenicity. In patients with PE who are hemodynamically stable, use of thrombolytics is controversial (even in the absence of pregnancy) and is generally discouraged. In patients who are hemodynamically unstable, but who cannot undergo systemic thrombolysis, surgical or percutaneous embolectomy are potential therapeutic options when clinical expertise for these procedures is available.[166]

Management of VTE in the peripartum period is complex and requires a detailed labor and delivery plan. The plan should take into consideration the risk of bleeding with full anticoagulation and the risk of recurrent VTE when anticoagulation is withheld. In addition, the need for regional anesthesia should be evaluated. A planned transition from LMWH to UFH near term may be considered, since UFH is more predictably reversed, has a shorter half-life, and is easily monitored.[167] A planned induction can ensure a controlled environment for delivery. However, given the unpredictable nature of labor, patients should be instructed to stop their injections at the first sign of labor and to contact their provider for further instructions.

Since a new VTE without treatment during the first month carries a 40% risk of recurrence, patients who are within two weeks of expected delivery should be considered for placement of an IVC filter.[168,169] Patients developing a clot between weeks two and four prior to delivery may be treated with intravenous UFH[170] or an IVC filter. Removable IVC filters can be placed in pregnancy, but they are usually placed above the renal veins. Intravenous UFH should be restarted postpartum as soon as possible.

Warfarin, an oral vitamin K agonist, crosses the placenta, is known to be teratogenic, and increases the risk of intracranial bleeding.[171] Use of warfarin for the treatment of VTE in pregnancy cannot be justified, given the availability of drugs with similar efficacy and better safety profiles.[30] Warfarin is detectable in breast milk, but in clinically insignificant amounts; hence, its use is considered safe in breastfeeding mothers.[172] Use of postpartum intravenous UFH or subcutaneous LMWH as a bridge to warfarin is warranted. It has been shown that use of warfarin alone, without antecedent use of heparin carries about a threefold risk of recurrent VTE.[173] Direct oral anticoagulants are not recommended for use in pregnancy or in women planning a pregnancy given a potential risk of bleeding or abortion. These drugs also are detected in breast milk, although no adverse effects were reported in the small number of exposed infants.[33]

PULMONARY ARTERIAL HYPERTENSION AND PREGNANCY

Pulmonary arterial hypertension (PAH) is an uncommon disorder that may affect women of childbearing age. PAH may present, or significantly worsen, during pregnancy. The hallmark of PAH is an increase in PVR. The increase in blood volume, cardiac output, and oxygen consumption, and the decrease in systemic vascular resistance seen in pregnancy, are poorly tolerated in patients with fixed PVR. These hemodynamic challenges are exacerbated at the time of delivery as a result of uterine contractions, autotransfusion, and increased sympathetic tone, as well as by large fluid shifts in the postpartum period. In affected patients, the normal physiologic changes of pregnancy may lead to right ventricular volume overload and, eventually, right ventricular failure and death.

Two large reviews of a total of 198 pregnancies in women with PAH revealed a mortality range from 17% in patients with idiopathic pulmonary arterial hypertension (iPAH) to 56% in women with other causes of pulmonary hypertension.[174,175] In contemporary case series in which patients were managed with pulmonary-specific vasodilators, substantially better outcomes have been reported. However, these reports may be limited due to publication biases.[176,177] Nearly all fatalities occur in the peripartum period as a result of heart failure, VTE, or sudden death. Due to the limited data and nature of the publications in this field, it remains uncertain if patients with less severe disease (i.e., lower mPAP or PVR) are at lower risk for death than are those with more severe disease, although this has been suggested in a number of reported series.[178,179] Currently, the recommendation remains that patients with even mild PAH should avoid pregnancy.[180] A decision to terminate a pregnancy or to induce delivery in the setting of PAH depends on the timing of diagnosis in gestation and the anticipated physiologic changes. In more advanced pregnancies, termination may not lessen risk of mortality or morbidity.

Use of medications for PAH in pregnancy is not well studied. Calcium channel blockers have been used successfully and are relatively safe in pregnant patients who have a vasodilator response demonstrated during right heart catheterization.[179] Unfortunately, loss of efficacy of calcium channel blockers over the long term limits their use, so pulmonary-specific vasodilators may be needed.[181] Pulmonary-specific vasodilators that have been used successfully during pregnancy include prostacyclins (treprostinil or epoprostenol) and phosphodiesterase (PDE) inhibitors (sildenafil and tadalafil).[182,183] Iloprost is teratogenic in animals, although there are reports of its use in pregnancy without teratogenicity;[184,185] however, such reports do not establish safety. Case reports describe successful use of inhaled nitric oxide (iNO) at the time of delivery, but risks to the fetus and neonate remain unclear. Since pregnancy is a prothrombotic state, anticoagulation for PAH should be used when indicated, including in those women with PAH who are on prolonged bed rest. LMWH is the preferred agent and should be continued in the postpartum period. Riociguat, an agent used for the treatment of chronic thromboembolic pulmonary hypertension, is known to be teratogenic in animals and is transferred via breast milk in animals.[186]

A multidisciplinary team that includes a PAH specialist should manage the patient throughout pregnancy and in the peripartum period. Carefully planned regional anesthesia may carry less risk than general anesthesia.[174,177] Cesarean delivery is unlikely to reduce anesthesia risk in women with PAH; in fact, cesarean delivery may be associated with a higher risk of medical complications in PAH, including VTE and atelectasis. Throughout pregnancy, close monitoring for worsening right heart failure is essential. Its development may herald the need for hospitalization, institution of bed rest, augmentation of therapy for PAH, emergent delivery, or termination of pregnancy.

Pulmonary hypertension is one of few disorders where pregnancy is a "contraindication." Hence, the best way to prevent the potentially fatal complications of PAH is to avoid pregnancy altogether. Contraception for prevention of future pregnancy is essential in patients with PAH mainly because of the high risk of mortality to both the mother and the fetus, but also because of the risk of teratogenicity in many of the drugs used to treat PAH, such as bosentan and ambrisentan. Hence, two forms of contraception are usually recommended. Options for contraception should be discussed in collaboration with a specialist familiar with both PAH and contraception. As patients with PAH are prothrombotic, estrogen-based contraception should be avoided. Similarly, intrauterine device placement carries a 5% risk of a vasovagal event, which may be fatal in patients with PAH. Thus, device implantation may require hospital admission.[163]

INTERSTITIAL LUNG DISEASES IN PREGNANCY

Only a minority of interstitial lung diseases (ILD) occur in women of childbearing age. In chronic ILD, preconception counseling is crucial to ensure appropriate disease control at the time of conception and use of medications with good efficacy and good safety profiles.[187] A multidisciplinary approach to these disorders is crucial to achieving improved outcomes.

Patients with a restrictive physiology may develop worsening symptoms in pregnancy due to a number of changes, including, for example, a significant increase in tidal volume. Outcomes often depend on the cause of restriction and disease progression during the course of the pregnancy. Patients with severe restriction should be assessed by an expert in obstetric anesthesiology prior to delivery, and a plan developed to avoid both high levels of anesthesia and use of the Trendelenburg position, when possible.

A variety of autoimmune and idiopathic systemic diseases may affect the lungs, producing pulmonary parenchymal and interstitial disease that may profoundly impact pregnancy.

Rheumatoid arthritis (RA) usually improves in the second and third trimesters[188] and flares in the postpartum period.[189] Convincing evidence that RA results in adverse pregnancy outcomes is lacking.

Systemic lupus erythematosus (SLE) may flare in pregnancy, especially in women with first pregnancies, renal involvement, and poor disease control at the time of conception.[190] The postpartum period confers a particularly high risk of lupus pneumonitis.[191] SLE increases the risk of complications of pregnancy and adverse fetal outcomes, including preeclampsia, spontaneous abortion, growth restriction, and preterm birth.[192–194]

Systemic sclerosis may have devastating consequences in pregnancy. Pregnancy planning and close monitoring can improve maternal and fetal outcomes. Renal crisis is a feared complication that is usually treated with angiotensin-converting enzyme (ACE) inhibitors. Given the high morbidity of this condition and the clear advantage of using ACE inhibitors over any other antihypertensive agents, use of these drugs can be justified, despite their known teratogenicity and the risk of neonatal renal dysfunction at birth. Pulmonary hypertension, another complication of systemic sclerosis, should be evaluated prior to pregnancy, and affected patients advised to avoid pregnancy.

Disease severity in polymyositis and dermatomyositis is likely a predictor of adverse fetal outcomes.[195] General anesthesia should be avoided in patients with polymyositis because of the risk of delayed muscle recovery, arrhythmias, heart failure, and aspiration.

Stable sarcoidosis likely has no significant effects on pregnancy outcomes. However, patients with pulmonary parenchymal disease, extrapulmonary sarcoidosis, or PAH, and those requiring drugs other than corticosteroids for disease suppression, tend to have more complicated pregnancies.[196]

Lymphangioleiomyomatosis (LAM) is a rare disorder that affects women of childbearing age. LAM is likely accelerated by exogenous hormones and pregnancy. Pregnancy in LAM is associated with a high incidence of pneumothorax and chylous effusion.[197] It is possible that LAM diagnosed during pregnancy may be a marker of disease severity.[198] The European Respiratory Society guidelines suggest that patients be informed of the risk of complications of LAM—for example, pneumothorax and chylous effusions—prior to pregnancy, as women with more severe disease may be more susceptible to these complications.[199]

The use of certain medications in pregnancy, such as corticosteroids, azathioprine, hydroxychloroquine, sulfasalazine, and intravenous immunoglobins, is necessary in certain clinical contexts. Use of tumor necrosis factor (TNF) antagonists is justifiable in rare circumstances. TNF antagonists have been implicated in cases of VATER (vertebral, anal, tracheal, esophageal, and radial anomalies) syndrome.[200] Cyclosporin A is unlikely to have teratogenic effects. Use of methotrexate, cyclophosphamide, mycophenolate mofetil, rituximab, leflunomide, and D-penicillamine should be avoided in pregnancy (see Table 93-3) and alternative agents employed in women planning a pregnancy.

PULMONARY EDEMA

Pulmonary edema during pregnancy is common, despite an overall young age of the patient population.[201] Plasma oncotic pressures decrease as gestation duration increases and decrease further in the postpartum period. Consequently, pulmonary edema may occur at lower-than-usual hydrostatic pressures during pregnancy. Given the profound hemodynamic changes at the time of labor, delivery, and the postpartum period, the vast majority of peripartum cases of pulmonary edema are reported postpartum. Intravenous fluid administration used to counteract the effect of vasodilation caused by regional anesthesia may contribute to its development. Autotransfusion of blood from the uterine circulation into the systemic circulation and the relief of inferior vena cava pressure are additional contributors.

Pulmonary edema in pregnancy can occur both with and without systemic hypertension.[202] A major cause associated with hypertension of pregnancy-related pulmonary edema is preeclampsia, which may be associated with left ventricular dysfunction, lower oncotic pressure, and possible capillary endothelial dysfunction. Tocolytic agents also have been associated with pulmonary edema. Treatment of pulmonary edema in pregnancy is essentially the same as in the nonpregnant population; however, pregnant women typically respond to lower doses of diuretics (e.g., an initial dose of 10 mg of furosemide administered intravenously). Nitroglycerine and hydralazine may be used. ACE inhibitors are known teratogens and should be avoided.

AMNIOTIC FLUID EMBOLISM

Amniotic fluid embolism (AFE), also known as anaphylactoid syndrome of pregnancy, is a rare but potentially catastrophic condition characterized by cardiopulmonary collapse and multiorgan dysfunction. An overall incidence has been reported of 1 in 40,000 births.[203] Mortality rates between 20% and 90% have been reported. Proposed risk factors for the development of AFE include advanced maternal age, complicated labor and delivery, obstetric interventions, uterine trauma, placental pathologies, and fetal distress.[204] The pathogenesis of AFE remains a subject of debate.

AFE presents as sudden hemodynamic instability, respiratory failure (cardiogenic or noncardiogenic pulmonary edema), disseminated intravascular coagulation, encephalopathy, and seizures. Detection of fetal squamous cells in the pulmonary vasculature is not a specific finding in AFE; it has been reported in asymptomatic women at term. Development of potential biomarkers to aid in timely diagnosis are being researched but are not yet validated for clinical practice.[205]

Treatment of AFE focuses on supportive measures and correction of the initial hemodynamic instability. Immediate cesarean section, which should be considered in cases of severe, refractory shock, should be promptly performed in hopes of improving maternal and fetal outcomes.[206] Use of recombinant factor VII,[207] iNO and other pulmonary vasodilators, exchange transfusion, extracorporeal membrane oxygenation (ECMO), and continuous venovenous hemofiltration (CVVH)[208,209] have been described, but little supportive evidence is available.

OVARIAN HYPERSTIMULATION SYNDROME

Severe ovarian hyperstimulation syndrome (OHSS) is an uncommon iatrogenic complication of exogenous gonadotropins used in assisted reproduction. Pulmonary complications include pleural effusions and VTE. In the severe stages, massive ovaries and ascites, large pleural effusions, oliguria, hemoconcentration, and VTE can be life threatening. Risk factors for OHSS include age older than 30 years, high serum estradiol, multiple ovarian follicles, and pregnancy.[210] Research suggests that vascular endothelial growth factor (VEGF), angiotensin II, and insulin-like growth factor play important roles in the pathogenesis of OHSS by increasing vascular permeability, which leads to vascular leakage of albumin, electrolyte imbalances, and rapid accumulation of extravascular fluid, including pleural effusions and ascites. Patients with OHSS are also at a higher risk for VTE and, in particular, a higher prevalence of upper extremity DVT, since estradiol-rich fluid drains through the thoracic duct into upper extremity veins.

Patients with severe symptoms of OHSS should have intravascular volume expansion, although the possibility of worsening intra-abdominal hypertension should be kept in mind. Current guidelines recommend paracenteses or culdocenteses for the management of symptoms as an outpatient.[211] Repeated large-volume paracenteses may improve renal perfusion by decreasing abdominal hypertension. Therapeutic thoracenteses also may be needed. Close monitoring for early signs of acute respiratory distress syndrome (ARDS), thromboembolism, and advanced renal failure is recommended. Thromboprophylaxis using UFH or LMWH should be initiated as soon as possible due to the high incidence of thromboembolic complications.[212]

SLEEP-DISORDERED BREATHING AND PREGNANCY

Sleep disruption and sleep disorders are common in pregnancy, specifically sleep-disordered breathing (SDB). While central sleep apnea (CSA) is uncommon in pregnant women, pregnancy appears to confer an increased risk for obstructive sleep apnea (OSA).

Mallampati scores[213] (relating tongue size to pharyngeal size and ease of intubation) increase as pregnancy progresses.[214] Due to the effect of estrogens and increased plasma volume, nasal patency is reduced. Upper airway size is smaller in pregnant women with[215] and without preeclampsia[216] compared with nonpregnant controls. The reduction in FRC may result in a tendency for upper airway collapse.[217] The effects of progesterone on minute ventilation may lead to a more negative inspiratory pressure, resulting in a vacuum effect on the upper airway. On the other hand, progesterone increases the electromyographic activity of the upper airway dilator muscles[218] and enhances their responsiveness to chemical stimuli.[219] In addition, reduced rapid eye movement (REM) sleep,[220] preference for assuming a lateral sleeping position in late gestation,[221] and increased minute ventilation may play protective roles. The balance of these factors favors an increased risk for SDB in pregnancy. Notably, snoring occurs in approximately 35% of pregnant women.[222] Objectively defined SDB is common even in low-risk women, occurring in 4% to 9% of all women in a multicenter sample in the United States.[223] Disease prevalence is significantly higher in pregnancies complicated by medical or obstetric conditions.[224–226] Lack of significant effort by obstetric providers in screening for SDB, even in obese patients, has been reported.[227] Hence, in clinical samples in large population-based studies that reported prevalence based on diagnosis codes, the prevalence was significantly lower at 0.1%,[228] suggesting poor screening, underdiagnosis, or underreporting.

OSA may improve in untreated women in the postpartum period;[229–231] however, it appears that at least 50% of women diagnosed with SDB in pregnancy continue to have an elevated apnea hypopnea index in the postpartum period.

Despite the high prevalence of this condition in pregnancy, screening remains complicated by the lack of a validated screening tool. The Berlin questionnaire, a widely used tool in screening the nonpregnant population, appears to have poor positive and negative predictive values in pregnancy.[232,233] Excessive daytime sleepiness correlates with other symptoms of SDB, such as snoring and witnessed apneas,[234] but Epworth Sleepiness Scale scores are not predictive of a diagnosis of SDB. Chronic hypertension, increased age, obesity, and snoring appear to have good predictive value for diagnosing OSA in high-risk populations;[235,236] however, the proposed models have not been validated in other populations including the high-risk population.

SDB is associated with a variety of medical disorders, which may have a major influence on pregnancy and its course. Gestational hypertension and gestational diabetes are associated with short-term maternal, fetal, and neonatal complications,[237–239] as well as long-term cardiovascular[240] and metabolic outcomes.[241] Hence, the association of these disorders with a modifiable disorder holds the promise of potentially preventing long-term, morbid outcomes.

Snoring and OSA have been shown to be associated with a variety of adverse pregnancy outcomes, including gestational hypertension,[222,228,242–244] gestational diabetes,[228,245–247] and cesarean deliveries.[222,248,249] Abnormalities in glucose metabolism, longer labor, and cesarean deliveries are also associated with short sleep duration.[222,246] Mechanistic studies are lacking, and the directionality of the association is not well clarified. The association of SDB with adverse fetal outcomes may be mediated by associated comorbidities. Growth restriction[243] and preterm birth[222,249,250] have been reported in association with snoring, OSA, or poor sleep in some studies. Case reports and case series suggest that fetal decelerations secondary to sleep apnea occur, but a study evaluating synchronized limited sleep studies and fetal monitors failed to show a significantly higher prevalence of late decelerations with obstructive events.[232]

A diagnosis of OSA also carries implications for labor and delivery management including upper airway patency; use of opioids peri-delivery, which may lead to respiratory depression and impact upper airway collapsibility; and monitoring in women receiving specific therapies such as magnesium sulfate, which may impact respiratory muscles.

Once diagnosed, treatment of OSA in the general population is recommended for patients with an apnea–hypopnea index (AHI) >15 or those with AHI >5, who have symptoms that respond to therapy, such as daytime sleepiness. For multiple reasons, specific guidelines on initiation of therapy in pregnancy are not available. To date, no trials have shown that treatment of OSA in pregnancy improves pregnancy or fetal outcomes, although treatment with CPAP in women with preeclampsia has shown significant hemodynamic improvement, even after one night of therapy.[251,252] This likely contributes to underscreening and underdiagnosis in this population.[227]

Alcohol and cigarette smoking avoidance carry additional pregnancy-specific benefits. Observational studies of positive airway pressure (PAP) therapy have shown improvement in daytime fatigue and daytime somnolence in pregnant women with OSA treated with CPAP which is re-titrated midpregnancy.[253] Auto-PAP may circumvent the need for repeat titration with pregnancy progression. In women with preeclampsia, small, randomized trials have shown that in-laboratory PAP therapy improves hemodynamics, uric acid, and cardiac output compared with untreated women.[251,254] Trials evaluating the effect of PAP therapy on pregnancy-specific cardiovascular and metabolic outcomes are sorely needed to help determine the "urgency" of starting PAP therapy in pregnancy.

Sleep-disordered breathing appears to improve in the postpartum period,[229] but about 50% of women with sleep-disordered breathing diagnosed in pregnancy will continue to have the disorder postpartum.[230,231] However, it is unclear whether persistence of sleep-disordered breathing in the postpartum depends on whether the disorder predated pregnancy or whether it developed in pregnancy.

PRECONCEPTION COUNSELING

Medical specialists often fail to adequately communicate and support women with chronic conditions around reproductive needs.[255] A pulmonologist's role in caring for reproductive-age women extends to preparing women with chronic lung disease for a successful pregnancy. Conversations with medical specialists need to occur in reproductive-age women with chronic lung disease who are sexually active, have a partner, and have children, regarding the possibility of and the implications of a pregnancy.[256]

According to the American College of Obstetricians and Gynecologists, the goal of prepregnancy care is to reduce the risk of adverse health effects for the woman, the fetus, and the neonate. This is achieved by working with the patient to educate her about a healthy pregnancy, optimize her health, and address potentially modifiable risk factors.[257] Since a woman's health changes throughout her lifespan, preconception counseling needs to occur multiple times during her reproductive years. Ideally, women should seek care before they attempt to get pregnant, and then as soon as they find out they are pregnant. Preconception counseling would assist in planning an optimal timing of pregnancy, avoiding unplanned pregnancies,[257] and implementing the best management strategies prior to conception and throughout pregnancy and the postpartum period.[258] Hence, periodic discussions about birth control methods are crucial.

Risk assessment includes the examination and communication of the risk of the chronic disease on pregnancy and perinatal outcomes, and vice versa.[259] Understanding and counseling patients on the risk of worsening of certain conditions (e.g., asthma, sleep apnea) during pregnancy or the recurrence of others (venous thromboembolism) can clarify expectations and assist the patient in making informed decisions about management choices and monitoring frequency.[257] Women should also be made aware of the risk of the treated or the untreated chronic condition on the health of the pregnancy and the fetus/newborn, which can guide decision-making regarding therapy choices.

Reviewing the risk of medications in pregnancy is another aim of preconception counseling.[257,260] Ideally, women would enter pregnancy on medications that are nonteratogenic. However, given the systematic exclusion of pregnant women from many interventional trials as recently as drug and vaccine trials in COVID-19, many drugs remain poorly examined for safety and efficacy in pregnancy. Hence, counseling would need to be provided with available data as well as any unforeseen potential risk.[261]

Genetic counseling is another key component of preconception counseling to properly inform the expectant mother and her family about potential risk of transmission of the disorder, and to clarify expectations for the offspring.

SUMMARY

Pregnancy constitutes a distinctive state in a woman's life that presents a number of unique physiologic, diagnostic, and therapeutic challenges. Pregnancy also offers an opportunity for many women to have meaningful interactions with the healthcare system and providers, including those focused on lung health and social habits. Prompt diagnostic and therapeutic interventions and close patient monitoring are warranted to help the pregnant woman tolerate the physiologic demands of pregnancy and the hemodynamic and respiratory stressors associated with labor and delivery. Deliberate postponement of a warranted clinical evaluation or intervention until after delivery is rarely the right approach.

CHAPTER 97

Pulmonary Complications of Intra-abdominal Disease

Hilary M. DuBrock
Sonja D. Bartolome

INTRODUCTION

Intra-abdominal pathology may have distant effects on the pulmonary vascular bed, the pulmonary parenchyma, or the pleural space. This chapter reviews the pulmonary complications of intra-abdominal disease, focusing on the pathology, epidemiology, clinical features, and management. Topics are organized according to the primary abdominal organ system in which the disease is centered.

PULMONARY COMPLICATIONS OF HEPATIC DISEASE

A number of respiratory complications of hepatic disease are well recognized, including portopulmonary hypertension (POPH), hepatopulmonary syndrome (HPS), hepatic hydrothorax (HH), and spontaneous bacterial empyema (SBEM). Each is discussed in the subsequent sections.

■ Portopulmonary Hypertension

POPH is defined as pulmonary arterial hypertension (PAH) occurring in the setting of liver disease, or more specifically, in the setting of portal hypertension.

Epidemiology and Pathogenesis

Approximately 2% to 6% of patients with decompensated liver disease develop POPH.[1–3] Based on multicenter, case-control studies, autoimmune hepatitis and female sex are identified risk factors for the development of POPH; therefore, the role of hormonal and immunologic influences in the pathogenesis of POPH is a focus of investigation.[4,5]

Patients with POPH have measurable alterations in levels of pulmonary vasoactive substances. For example, prostacyclin is a potent pulmonary vasodilator that also has antithrombotic and antiproliferative properties; levels of prostacyclin are decreased in the lungs of patients with PH. In patients with POPH, loss of endothelial prostacyclin synthase expression compared with normal controls has been demonstrated.[6] Endothelin 1 (ET-1), a pro-proliferative and vasoconstrictive agent implicated in the pathophysiology of other types of PH, has also been shown to be increased in the circulation of patients with POPH.[7] Bone morphogenetic protein 9 (BMP9), an endothelial quiescence factor produced in the liver, is a sensitive, specific, and prognostic biomarker of POPH. Circulating levels of BMP9 are reduced in POPH as well as HPS.[8,9]

Histologically, POPH appears to be very similar to other types of PH. POPH is a precapillary pulmonary arteriopathy involving multiple layers of the vessel; specifically, POPH is characterized by smooth muscle hypertrophy, adventitial proliferation, and endothelial cell proliferation. In addition, the plexiform lesions characteristic of other types of PH have been demonstrated in patients with POPH (Fig. 97-1).[10]

The microvascular changes in POPH result in a pulmonary circulation characterized by increased resistance and low capacitance—the antithesis of the normal pulmonary vascular physiology, which is characterized by a low-pressure and high-flow state. The altered physiology constitutes an increased workload to the right ventricle (RV). Early in the disease process, the RV hypertrophies and increases its stroke volume. Over time, these changes become maladaptive, and the RV dilates and becomes dysfunctional. At this stage, the patient demonstrates progressive right ventricular failure. The clinical course of POPH is similar to that seen in other types of PH (Chapter 72), justifying its placement in Group 1 of the World Health Organization Classification (Table 97-1).[11] However, the concomitant presence of end-stage liver disease, with accompanying fluid retention, hypoalbuminemia, coagulopathy, renal dysfunction, and gastrointestinal bleeding, complicates the clinical management of patients.

Clinical Features

Patients with POPH may present with complaints of fatigue and dyspnea with exertion, which are later accompanied by signs and symptoms of right ventricular failure, such as jugular venous distension, lower extremity edema, presyncope, and syncope. The diagnosis can be particularly elusive in the cirrhotic patient, who may have edema from portal hypertension and a spectrum of hemodynamic disturbances. Consequently, the diagnostic workup must be performed carefully to avoid a misdiagnosis of POPH.

The most common hemodynamic derangement in patients with liver disease is not PH, but rather, a state of systemic vasodilation and high cardiac output (CO) induced by splanchnic vasodilation.[2] In these patients, hemodynamics are characterized by increased mean pulmonary artery pressure (mPAP), high CO, low pulmonary capillary wedge pressure (PCWP), and reduced pulmonary vascular resistance (PVR). Affected patients do not have small vessel arteriopathy, but rather, increased pressure resulting from high flow through the pulmonary circulation. This hemodynamic pattern is evident in approximately 35% of liver transplant candidates and is not associated with a poor outcome.[2]

A second abnormal hemodynamic profile present in patients with liver disease reflects volume overload or diastolic dysfunction.

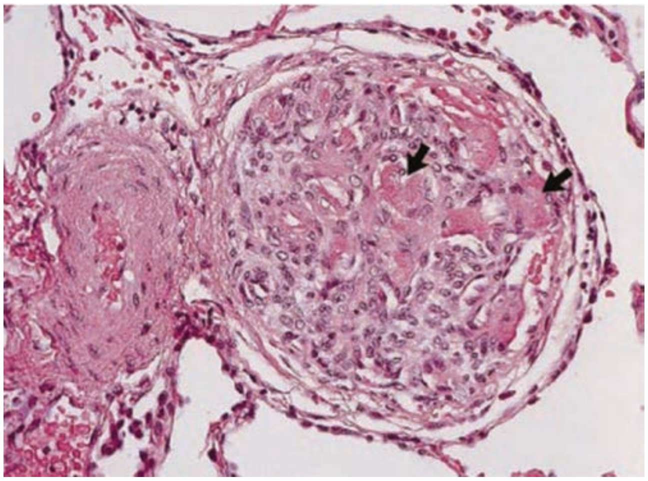

Figure 97-1 Autopsy specimen from a 55-year-old female with cryptogenic cirrhosis and portopulmonary hypertension, showing the plexiform lesion common in pulmonary arterial hypertension. The *arrows* show acute platelet-fibrin thrombi within the plexiform lesion. *(Reproduced with permission from Krowka MJ, Edwards WD. A spectrum of pulmonary vascular pathology in portopulmonary hypertension. Liver Transpl. 2000;6(2):241–242.)*

TABLE 97-1 Updated Clinical Classification of Pulmonary Hypertension (PH)

- Group 1, pulmonary arterial hypertension (PAH)
    - Idiopathic
    - Hereditable
    - Drug- and toxin-induced
    - PAH associated with:
        - Connective tissue disease
        - Human immunodeficiency virus
        - Portal hypertension
        - Congenital heart disease
        - Schistosomiasis
    - PAH long-term responders to calcium channel blockers
    - AH with overt features of venous/capillaries (PVOD/PCH) involvement
    - Persistent PH of the newborn syndrome
- Group 2, PH due to left heart disease
    - PH due to heart failure with preserved ejection fraction
    - PH due to heart failure with reduced ejection fraction
    - Valvular heart disease
    - Congenital/acquired cardiovascular conditions leading to postcapillary PH
- Group 3, PH due to lung diseases and/or hypoxia
    - Obstructive lung disease
    - Restrictive lung disease
    - Other lung disease with mixed obstructive/restrictive pattern
    - Hypoxia without lung disease
    - Developmental lung disorders
- Group 4, PH due to pulmonary artery obstructions
    - Chronic thromboembolic PH
    - Other pulmonary artery obstructions
- Group 5, PH with unclear and/or multifactorial mechanisms
    - Hematologic disorders
    - Systemic and metabolic disorders
    - Others
    - Complex congenital heart disease

Modified with permission from Simonneau G, Montani D, Celermajer DS, et al. Haemodynamic definitions and updated clinical classification of pulmonary hypertension. Eur Respir J. 2019;53(1):1801913.

With this profile, pulmonary pressures may be elevated, but CO and PCWP are also increased; in addition, PVR is low, indicating pulmonary *venous* hypertension from elevated left heart filling pressures, rather than small vessel pulmonary arteriopathy.

Finally, the third hemodynamic profile that defines POPH is characterized by an elevated pulmonary artery pressure, normal PCWP, high PVR, and high, normal, or low CO—depending on the degree of resultant right ventricular failure and liver disease (Table 97-2).

Not infrequently, patients may present with a *combination* of these hemodynamic profiles, for example, POPH with volume overload. In this case, an increased transpulmonary gradient (TPG) >12 mm Hg (TPG $=$ mPAP $-$ PCWP) may suggest existence of combined volume overload and pulmonary arteriopathy. To characterize such complexity, many have suggested that the hemodynamic definition of POPH be expanded to include mPAP >20, TPG >12, and PVR >3 Wood units.[3,11]

TABLE 97-2 Hemodynamic Patterns in Patients with Liver Disease

	mPAP	CO	PCWP	PVR	TPG
High cardiac output and vasodilated	↑	↑↑	↓	↓↓	N ↑
Fluid overload or diastolic dysfunction	↑	↑	↑↑	N	N
Portopulmonary hypertension	↑	↷	N	↑	↑

mPAP, mean pulmonary artery pressure (normal, <21 mm Hg); PCWP, pulmonary capillary wedge pressure (normal, ≤ 15 mm Hg); CO, cardiac output (normal, 4–6 L/min); PVR, pulmonary vascular resistance (normal, <3 Wood units: [mPAP–PWCP]/CO); TPG, transpulmonary gradient (normal, <12: mPAP–PCWP); N, normal.

Diagnosis

To establish a diagnosis of POPH, objective evidence (increased hepatic vein-free pressure to wedge pressure gradient) or clinical evidence of portal hypertension must be present. The presence and severity of POPH is not related to liver disease severity, and POPH can develop in patients with noncirrhotic portal hypertension. The diagnosis of POPH is often first suggested by an echocardiogram, but echocardiography is confounded by the previously noted hemodynamic changes seen in cirrhosis.[12] Therefore, an echocardiographically estimated peak pulmonary artery systolic pressure >38 mm Hg or signs of significant RV dysfunction should trigger confirmatory right heart catheterization.[13] This threshold was 100% sensitive in detecting POPH.[13]

Clinical Course

Patients with POPH appear to have worse clinical outcomes than patients with other types of PH. The French registry recorded the outcomes of 154 patients with POPH and included both treated and untreated subjects. Five-year survival was reported in 68% of patients. Multivariate analysis identified advanced liver disease severity and lower cardiac index as independent risk factors for mortality.[14]

The REVEAL (Registry to Evaluate Early and Long-term PAH Disease Management) registry for PH is a multicenter, observational study that has recorded the outcomes of 174 patients with POPH—the largest cohort to date. The data show that patients with POPH have poorer survival and higher all-cause hospitalization rates compared with patients with idiopathic or familial PH, despite the group with POPH having a more favorable initial hemodynamic profile than the others (Fig. 97-2).[15] Furthermore, when data were analyzed to derive a risk score for 1-year mortality for all patients presenting with PH, POPH demonstrated a hazard ratio of 3.6 compared to other etiologies.[16]

Management

POPH is classified as group 1 PAH, and, therefore, is a treatable category of PH using FDA-approved drugs.[11] However, POPH was excluded from the majority of clinical trials assessing use of these agents. Therefore, most data on treatment of POPH are derived from case series and single-center studies, as summarized in the following sections.

Endothelin Receptor Antagonists The endothelin receptor antagonists bosentan, ambrisentan, and macitentan are established treatments in group 1 PAH. Endothelin is a pulmonary vasoconstrictor and pro-proliferative agent, and its antagonism has been shown to improve exercise capacity and hemodynamics in patients with PH.

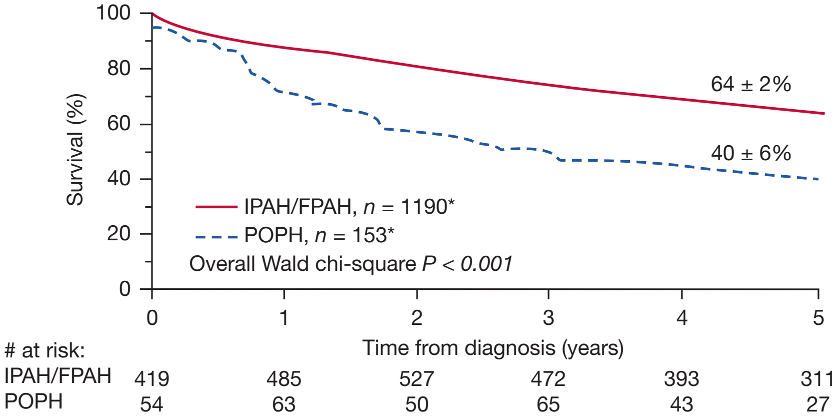

Figure 97-2 Five-year survival from the time of diagnosis of POPH versus IPAH/FPAH. *(Data from REVEAL registry. Only patients enrolled within 5 years of diagnosis were included in the 5 years survival from diagnosis curve. Chest. 2012;141(4):905–915.)*

Bosentan is a dual endothelin receptor antagonist (ET_A and ET_B). In small, single-center, uncontrolled, observational trials, POPH patients treated with bosentan have shown improvements in exercise capacity and hemodynamics.[17–19] Use of bosentan has been limited in this group due to its well-described hepatotoxicity occurring in a minority of patients (∼10%) with PH, but no underlying liver disease. The hepatotoxicity is likely related to the agent's inhibition of a bile salt transporter; the toxicity is usually reversible with drug discontinuation.[20]

Ambrisentan is a selective ET_A antagonist and is also FDA approved for the treatment of group 1 PAH. Hepatotoxicity has not been reported with this agent. A prospective, multicenter, open-label trial of ambrisentan in POPH reported a significant improvement in mPAP, PVR, and cardiac index with treatment with no significant change in 6-min walk distance.[21]

Macitentan is a newer dual endothelin receptor antagonist that is FDA approved for the treatment of group 1 PAH. A phase 4, multicenter, randomized, controlled trial found that macitentan significantly improved PVR by 35% and had a favorable hepatic safety profile but did not significantly improve 6-min walk distance.[22]

Phosphodiesterase Type 5 Inhibitors Two phosphodiesterase type 5 inhibitors (PDE5i), sildenafil and tadalafil, are currently FDA approved for the treatment of group 1 PAH. PDE5i act via the nitric oxide pathway and vasodilate the pulmonary vascular bed by inhibiting breakdown of cyclic guanosine monophosphate. Small, uncontrolled, observational trials reveal that sildenafil in POPH increases 6-min walk test distance and lowers levels of N-terminal pro b type natriuretic peptide, both of which correlate with a better prognosis in patients with PH.[23] The reported hemodynamic response has been mixed, with one observational trial reporting an improved PVR in three of five patients at 1 year,[24] and another showing improved PVR in all nine patients studied at follow-up, which ranged from 95 to 282 days.[25]

Soluble Guanylate Cyclase Stimulators Riociguat is the only soluble guanylate cyclase stimulator approved for the treatment of PAH. Mechanistically, it works by directly stimulating soluble guanylate cyclase to produce cyclic guanosine monophosphate. In PAH, riociguat improves 6-min walk distance, PVR, N-terminal pro b type natriuretic peptide levels, functional class, and time to clinical worsening. Although it was a small percentage (3%) of the cohort, this clinical trial did include POPH patients.[26]

Prostacyclin Receptor Agonists Selexipag is an oral selective IP prostacyclin receptor agonist approved for the treatment of PAH. In a multicenter, randomized clinical trial, selexipag met its primary composite endpoint of reducing mortality or a complication related to PAH primarily by reducing disease progression and hospitalization. POPH patients were not included in this pivotal trial, and there is little evidence supporting the use of selexipag in this subgroup.[27]

Prostacyclins Prostacyclin analogues are key agents in the treatment of PAH, and they are considered by many to be the agents of choice for the "sickest" patients. These drugs may be given orally, continuously via subcutaneous or intravenous routes, or intermittently in inhaled form. Current FDA-approved prostacyclins for intravenous use are epoprostenol and treprostinil. Treprostinil is also available for oral, subcutaneous, or inhalational administration. In the United States, iloprost is available only in the inhaled form, although it is given intravenously in Europe.

Uncontrolled, single-center series have consistently demonstrated that prostacyclin infusions result in significant improvements in mPAP, CO, and PVR in patients with POPH.[28–30] Furthermore, prostacyclin infusions have been used successfully to improve hemodynamics in patients with POPH in advance of safe pursuit of liver transplantation.[30–32] Limited data are available to support the use of oral or inhaled prostacyclins for POPH. Although iloprost has been shown to improve hemodynamics acutely, long-term effects are less certain.[33]

Liver Transplantation The history of liver transplantation in the setting of POPH is controversial. Early in the history of liver transplantation, the diagnosis of POPH was made in the operating room at the time of the procedure. Patients were neither previously treated for the disease nor under the care of a medical team familiar with critical care of patients with POPH. Not surprisingly, intraoperative mortality from decompensated right ventricular failure was high.[34] Long-term outcome also was adversely affected. Those with severe POPH had a 9-month posttransplant survival rate of 58%.[35] Consequently, severe POPH was considered a contraindication to liver transplantation.

With increasing clinical experience and the advent of new treatments for PH, transplant centers began to report both successful liver transplants in patients with POPH, and, in some, regression of POPH following surgery.[36,37] In 2006, a case series of eight sequential patients with POPH were treated with IV epoprostenol. Of the eight, seven had significant hemodynamic improvement. Six of the seven were listed for liver transplantation, and four of those listed were successfully transplanted. Of those transplanted, survival was 100% at 5 years.[26,32] Furthermore, in a retrospective study based on screening of patients with POPH with RHC, 5-year survival for those not transplanted or treated for PH was 15%, whereas 5-year survival for those who were treated for PH and transplanted was 64%.[33]

Because of the initial poor experiences with POPH patients undergoing liver transplantation, retrospective studies sought to identify risk factors for perioperative mortality. These series have suggested that if a patient has mPAP <35 mm Hg and normal right ventricular function, perioperative mortality approaches that of patients without POPH. However, if mPAP is >50 mm Hg at the time of transplant, mortality approaches 100%.[34,36]

Because there is a role for liver transplantation in selected patients with POPH, the United Network for Organ Sharing allows for upgrade points in the model for end-stage liver disease (MELD) score, facilitating liver transplantation. The MELD system prioritizes liver transplantation for the sickest patients, and the exception system allows extra points for those whose mortality risk is not reflected in their MELD score. Currently, the guidelines indicate that if a patient has a confirmed diagnosis of POPH and they are treated with pulmonary vasodilator therapy to attain mPAP <35 and a PVR <5 Wood units or mPAP of 35 to 45 with a PVR <3 Wood units, they are eligible for a MELD exception, or waitlist priority upgrade.[38]

Liver transplantation in these patients should be performed at a center experienced in pulmonary vascular disease, as the perioperative course may be complicated. Even in patients without POPH, a well-described "reperfusion syndrome" may occur at the time of allograft reperfusion. Reperfusion syndrome may cause acute elevations in mPAP and may induce acute, decompensated right ventricular failure in patients with POPH.[39] The use of intraoperative prostacyclin infusion, inhaled nitric oxide, or intravenous milrinone has been described in this emergent setting; results have been mixed.[3,40,41]

Limited data exist regarding the clinical course of POPH after liver transplantation. One-year posttransplant survival rates vary from 63% to 88%, while reported 5-year survival rates vary from 54% to 87%.[42] POPH progression, stability, improvement, and resolution have all been reported. In most of the cases, patients are able to wean from their prostacyclin infusion over a period of months, but some remain on oral pulmonary vasodilators. Available data suggest that 40% to 50% of patients may be able to be weaned from all pulmonary vasodilators, given enough time.[43,44]

Summary

POPH is an uncommon complication of liver disease, which is characterized by a progressive pulmonary arteriopathy, and which may result in right ventricular failure and death. Patients with POPH appear to have an increased mortality compared with those with similar levels of liver disease or with other types of PH. Specific protocols for optimal use of pulmonary vasomodulators for POPH are under investigation. However, patients exhibit improved hemodynamics and exercise capacity when receiving therapy for PH. The role of liver transplantation in this setting is arguable, but transplantation may be performed in carefully selected patients and may cure not only their liver disease, but also their POPH.

■ Hepatopulmonary Syndrome

HPS is a liver-induced pulmonary vascular disorder characterized by abnormal arterial oxygenation and a widened alveolar–arterial oxygen gradient. The widened gradient is the result of intrapulmonary vasodilation in the presence of hepatic disease or portal hypertension. Clinically, intrapulmonary vasodilation may occur with or without overt hypoxemia, depending on the severity of the disease. HPS increases mortality in patients with liver disease, is without specific therapy, and is completely curable with liver transplantation. Therefore, unlike POPH, the presence of significant HPS is considered an indication for liver transplantation.[3]

Epidemiology and Pathogenesis

The prevalence of HPS is reported as 4% to 32% in cohorts of cirrhotic patients undergoing liver transplant evaluation.[45,46] The pathogenesis is poorly understood but is thought to involve angiogenesis, as well as inadequate synthesis or metabolism by the impaired liver of pulmonary vasoactive substances, such as nitric oxide, prostaglandins, vasoactive intestinal peptide, endothelin, calcitonin, glucagon, substance P, and atrial natriuretic factor.[47] Nitric oxide has long been implicated in the pathophysiology of HPS, given its known pulmonary vasodilatory effects.[48,49] Endothelin also has been implicated in the pathophysiology of HPS. Although endothelin is often thought of as a vasoconstricting agent, and its inhibition is a common therapy for PH, endothelin's actions vary widely by the receptor to which it attaches. When endothelin 1 binds to the ET_A receptor, the effect is pulmonary vasoconstriction. However, when endothelin 1 attaches to the ET_B receptor, it enhances the activity of endothelial nitric oxide synthase and causes pulmonary vasodilation. In experimental models of HPS, the ET_B receptor has been demonstrated to be upregulated; in these animal models, the experimental HPS was reversed by ET_B receptor blockade.[50,51]

Whatever the underlying mechanism of HPS, patients develop IPVD that causes a ventilation–perfusion mismatch and diffusion limitation to oxygenation because of an increase in vascular diameter. The normal pulmonary capillary is 8 to 15 μm in diameter, but in HPS capillaries may dilate to 15 to 100 μm in diameter. Because of this alteration in the normal structure of the alveolar–capillary units, inhaled oxygen does not reach the center of the blood vessel, and some blood returns to the left heart still deoxygenated. In a very rare subset of patients the hypoxemia is the result of true shunt, and arteriovenous malformations occur with no communication with alveoli.

Clinical Features

Most patients with HPS present with symptoms of chronic liver disease, and a minority present with dyspnea as their primary symptom. Therefore, a high index of suspicion should be maintained to make a timely diagnosis. Patients may complain of platypnea (dyspnea with standing) or have the physical examination finding of orthodeoxia, which is defined as a Pa_{O_2} decrease of 5% or 4 mm Hg upon standing.[52] This combination of findings is attributed to the increases in intrapulmonary vasodilatation in the lung bases and, therefore, increased ventilation–perfusion mismatch in the standing position. Although the combination of findings is well described in HPS, it is neither common nor pathognomonic.[52]

On physical examination, patients with HPS may present with spider angiomata, clubbing on the digits, and peripheral cyanosis.[45] The chest radiograph is often normal, but it may reveal bibasilar increased interstitial markings, which may reflect vascular dilation in the bases.[53] Pulmonary function testing often reveals reduced diffusion capacity for carbon monoxide, which is out of proportion to other pulmonary function abnormalities.[54]

HPS has been reported in patients with both acute and chronic liver diseases. Most commonly, it is described in cirrhotics, but HPS has also been documented in the setting of noncirrhotic portal hypertension and acute and chronic hepatitis.[3,55] The severity of HPS does not correlate with the severity of the underlying liver disease.

Diagnosis

The diagnosis of HPS requires the presence of (1) cirrhosis or portal hypertension, (2) a widened age-corrected alveolar–arterial oxygen gradient (>15 mm Hg or >20 mm Hg if age >64), and (3) demonstration of intrapulmonary vasodilatation on a bubble contrast–enhanced transthoracic echocardiogram.

Bubble contrast–enhanced echocardiogram is the most sensitive test for the detection of intrapulmonary vasodilation. However, echocardiography is a qualitative examination in which saline is agitated and then injected into a peripheral vein. The agitation causes formation of microbubbles that are at least 15 μm in diameter. In normals, the microbubbles are trapped within the pulmonary capillary bed and absorbed. However, if intrapulmonary vasodilation is present, the bubbles traverse the pulmonary capillaries and appear in the left atrium approximately three to six cardiac cycles after their injection. Echocardiography can also identify an intracardiac shunt, in which case, the bubbles appear in the left atrium within three cardiac cycles.[56]

Intrapulmonary vasodilation may also be detected by technetium-labeled macroaggregated albumin lung perfusion scanning. In this examination, technetium-labeled macroaggregated albumin is injected intravenously and uptake is detected in the lungs and brain. In the absence of intrapulmonary or intracardiac shunt, the tracer is trapped within the pulmonary circulation and very little is observed on brain imaging. A fractional brain uptake >5% is considered abnormal. Although macroaggregated albumin scanning allows quantification of the shunt, it cannot differentiate between intracardiac and intrapulmonary shunt. One additional advantage of the macroaggregated albumin scan is that it is specific for HPS, even in the presence of intrinsic lung disease. Therefore, it may help to distinguish hypoxemia from HPS from that due to pulmonary parenchymal disease if both are present. Although macroaggregated albumin scanning is less sensitive than transthoracic echocardiography for detecting the presence of HPS, the magnitude of the shunt detected correlates poorly with the degree of hypoxemia.[56]

Arterial blood gases that quantify Pa_{O_2} and the alveolar–arteriolar oxygen gradient for HPS should be obtained with the patient seated at rest and breathing room air. Due to disease-associated alterations in ventilation–perfusion matching with positional changes, along with a propensity for increased pulmonary vasodilatation in the lung bases, hypoxemia may worsen with standing and improve in the supine position. Guidelines published in 2004 by the European Respiratory Society Task Force and recently reiterated by the International Liver Transplantation Society suggest subclassification of HPS according to level of hypoxemia: $Pa_{O_2} \geq 80$ mm Hg is considered mild; $Pa_{O_2} < 80$ mm Hg but ≥ 60 mm Hg is considered moderate; $Pa_{O_2} < 60$ mm Hg but $Pa_{O_2} \geq 50$ mm Hg is considered severe, and < 50 mm Hg is considered very severe.[3,57]

Since pulse oximetry is insufficiently sensitive as a noninvasive screening test, contrast-enhanced echocardiogram and arterial blood gas testing are needed for diagnosis.[58]

Clinical Course

The presence of significant HPS decreases exercise capacity, impairs quality of life, and increases mortality compared with patients without HPS who have a similar severity of liver disease.[52] Furthermore, the majority of patients with HPS progress over time; the average rate of decline in resting Pa_{O_2} is 5 mm Hg/year.[59] In one multicenter, prospective study, patients with HPS had a doubling in risk of death compared with patients without HPS, despite no differences in rates of listing for liver transplantation, performance of liver transplantation, age, sex, or race.[52] Guidelines recommend screening for HPS at the time of liver transplant evaluation.[3,60]

Management

No medical therapy has been shown to improve patients with HPS. Many agents have been tried unsuccessfully or with mixed results, including norfloxacin, β-blockade, nitric oxide inhibitors, nitric oxide, glucocorticoids, cyclooxygenase inhibitors, indomethacin, somatostatin, sorafenib, cyclophosphamide, and plasma exchange.[47,61,62] Supplemental oxygen is often administered in HPS and may ameliorate the symptoms of hypoxemia.

Liver Transplantation Liver transplantation is the only therapy proved to resolve HPS. Long-term follow-up reveals significant improvement or resolution of HPS in 85% of patients who undergo liver transplantation.[63–65] The time required for improvement in oxygenation is variable and may take up to 1 year or longer.

Hypoxemia due to HPS may complicate the postoperative course in liver transplantation. In a retrospective analysis of the United Network of Organ Sharing data, the finding of a preoperative $Pa_{O_2} \leq 44$ mm Hg was associated with increased postoperative mortality.[66] However, other reports suggest that liver transplantation may be safely performed in patients with HPS, including those with severe hypoxemia.[67,68]

Because of the increased mortality associated with HPS and the favorable outcome for liver transplantation, the United Network of Organ Sharing has instituted a MELD exception guideline for affected patients: if the diagnosis of HPS is confirmed with bubble contrast echocardiography and the patient's is $Pa_{O_2} < 60$ mm Hg, an application for a MELD exception may be submitted. The upgrade increases the patient's MELD score to 3 less than the median MELD score at transplant for transplant recipients within the transplant center's donor service area, regardless of the severity of liver disease.[69]

Summary

HPS is a liver-induced pulmonary vascular disorder characterized by intrapulmonary vascular dilation resulting in ventilation–perfusion mismatch and a diffusion limitation for oxygenation. No known medical treatment for HPS exists, and patients with HPS have a poorer prognosis than patients with liver disease without HPS. HPS is an indication for, and is curable by, liver transplantation.

■ Hepatic Hydrothorax

HH is defined as a pleural effusion (typically >500 mL) occurring in a patient with liver disease in the absence of an alternative cardiac or pulmonary source. HH may complicate management of cirrhosis, and it may contribute to morbidity.

Epidemiology and Pathophysiology

HH occurs in 6% to 10% of patients with end-stage liver disease. Its development is related to anatomic defects in the diaphragm, which allow fluid migration down a pressure gradient from the peritoneum into the negative pressure environment of the pleural space.[70,71] It is postulated that as ascites develops, intra-abdominal pressure increases and strains diaphragmatic tissue, which then weakens. Eventually, pleuroperitoneal blebs form and then rupture, creating a communication between the abdominal and pleural cavities. In general, these blebs are <1 cm in diameter and are more common in the right hemidiaphragm, perhaps as a consequence of the more muscular construct of the left hemidiaphragm.[72] Although HH usually occurs in the setting of ascites, HH may be present even when clinically apparent ascites is absent, making the diagnosis more challenging.[73,74]

Clinical Features

Clinical manifestations of HH include dyspnea, pleuritic chest pain, and nonproductive cough. HH is right sided in 85% of patients, left sided in 13%, and bilateral in 2%.[74] Pleural fluid analysis generally reveals characteristics consistent with ascitic fluid, with slight alterations due to the increased ability of the pleura to absorb free water. HH is transudative, with a total protein level <2.5 g/dL, lactate dehydrogenase fluid-to-serum ratio <0.5, and a total protein fluid-to-serum ratio <2.5. The serum-to-fluid albumin gradient is generally >1.1 g/dL.[70,74,75] Occasionally, patients present with hepatic chylothorax. In these cases, the fluid is also transudative, but the fluid-to-serum triglyceride level exceeds 1; in addition, the fluid-to-serum cholesterol ratio is high. Hepatic chylothorax is thought to arise from chylous ascites entering the pleural space through the previously described mechanism.[76]

Diagnosis

Diagnostic thoracentesis should be performed in the setting of hepatocellular carcinoma, fever, or pain. A prospective series investigating the clinical utility and risks of thoracentesis in the cirrhotic population demonstrated that 30% of patients have an alternative diagnosis to uncomplicated HH. The most common alternative diagnoses are SBEM (see below), pleural tuberculosis, or adenocarcinoma.[77] In another large prospective series, thoracentesis was safely performed in cirrhotic patients with mild coagulopathy (PT or PTT ≤2 × normal, platelet count of 50,000–99,000 [per μL]) without prophylactic plasma or platelet transfusion. Hence, the presence of a mild coagulopathy should not delay diagnostic evaluation.[78]

Spontaneous Bacterial Empyema

SBEM occurs when a previously existing HH becomes infected. The empyema portion of this term is a misnomer because diagnosis does not require purulent material in the pleural cavity, but rather refers to an infection diagnosed by pleural fluid cell count analysis. The diagnosis is made if the pleural fluid has a positive culture and the polymorphonuclear neutrophil count is >250 cells/mm^3, or, if the culture is negative, the fluid contains >500 polymorphonuclear neutrophils/mm^3. The sensitivity of the pleural fluid culture increases from 33% to 77% if blood culture bottles are directly inoculated at the bedside during the procedure.[77] The incidence of SBEM has been reported as 13% in hospitalized patients with cirrhosis and a pleural effusion. Simultaneous spontaneous bacterial peritonitis is a risk factor for the development of SBEM; however, up to 40% of cases are not associated with spontaneous bacterial peritonitis.[77,79] Mortality has been reported as high as 20%. Therefore, clinicians should maintain a high index of suspicion to ensure the diagnosis is made in a timely manner.

The most commonly identified bacterial pathogens in SBEM are *Escherichia coli*, *Klebsiella pneumoniae*, *Streptococcus* species, and *Enterococcus* species.[80] Third- or fourth-generation cephalosporins are the empiric treatment of choice until culture data are obtained. Chest tube insertion is not recommended unless frank pus is present in the pleural cavity, given the risks of complications from the procedure in this patient population.

Management

Medical and surgical interventions are employed in the management of HH. Each is described briefly in the subsequent sections.

Diuretics As is the case in management of ascites, the mainstay of treatment of HH is the establishment of negative sodium balance. Current guidelines for management of ascites call for a diet that entails 2 g/d sodium restriction, along with the administration of furosemide and spironolactone in a ratio of 40 mg of furosemide to 100 mg of spironolactone daily. Despite aggressive medical management, 20% to 26% of cirrhotics with ascites are refractory to medical treatment.[82]

Thoracentesis Thoracentesis can be performed safely in patients with cirrhosis, even in the face of mild coagulopathy. Therefore, therapeutic thoracentesis may be performed to relieve dyspnea in patients with HH that is refractory to dietary sodium restriction and diuretics. Traditionally, removal of no more than 2 L of fluid is recommended at one time because of the risk of re-expansion pulmonary edema and hypotension. However, whether the risks of large-volume thoracenteses apply to this population of patients is unclear. Large-volume thoracenteses have been performed safely with close patient monitoring and measurement of end-expiratory pleural pressure. The recommended goal for end-expiratory pleural pressure is >-20 cm H_2O.[84] Data in support of use of intravenous infusion of albumin to avoid hypotension during thoracentesis are lacking.

Large-volume paracentesis may also be considered for patients in respiratory distress in patients due to ascites or HH. Paracentesis improves dyspnea and lung function within 2 h of fluid removal. The procedure may provide symptomatic relief for patients with HH and a lower risk than thoracentesis.[85]

Tube Thoracostomy Although tube thoracostomy may seem an attractive option in patients with recurrent HH, multiple reports have confirmed a high complication rate. Specifically, pneumothorax, hemothorax, empyema, electrolyte abnormalities, and hepatorenal syndrome have all been reported. In one series of 59 patients with cirrhosis and chest tube placement, a complication rate of 80% and mortality rate of 27% were reported. Therefore, this intervention should be avoided.[86] Newer studies evaluating the use of indwelling pleural catheters in HH have reported lower complication rates of 36%, suggesting that indwelling pleural catheters may be considered in a select group of patients with refractory HH as a palliative treatment.[87]

Transjugular Intrahepatic Portosystemic Shunt Transjugular intrahepatic portosystemic shunt (TIPS) reduces portal pressure by creating a shunt between the portal and hepatic veins. TIPS placement is the treatment of choice for a refractory HH. In a series of 73 patients with refractory HH who underwent TIPS placement, 79% had a complete or partial response to the procedure; long-term survival rates were consistent with the severity of liver disease.[88]

TIPS placement is not appropriate for all patients, despite its success in patients with HH and ascites. Patients with severely decompensated liver disease may decompensate further following the procedure because of the shunt's negative effect on hepatic blood flow. In addition, shunting blood from the portal to hepatic vein increases right atrial and pulmonary artery pressure and may further compromise patients with right-sided heart failure or PH.[89] Therefore, moderate to severe pulmonary hypertension is considered a contraindication for TIPS placement.[90] In a high-risk patient, the option of liver transplantation should be discussed before proceeding with TIPS, since transplantation can be used as a "safety net" for clinical decompensation. In a carefully selected population with refractory HH, TIPS is the standard of care.

Surgical Intervention Small case series have documented success in treating HH using open thoracotomy or video-assisted thoracoscopy.[91,92] The procedures are based on identification of diaphragmatic defects and their closure with subsequent pleurodesis. Surgical pleurodesis has a documented success rate of 73% to 100% in preventing recurrence of HH; however, high complication rates have been noted. In one series of 18 patients, a success rate of 48% was noted, but 3-month mortality was 38.9%.[93] Therefore, although video-assisted thoracoscopy with pleurodesis may be an option for patients with refractory HH, larger trials are needed to assess safety before this procedure is considered a standard recommendation.

Liver Transplantation Liver transplantation is curative for HH and should be the primary intervention for patients with refractory disease. The presence of HH does not affect ventilator days in the immediate postoperative period, nor does it increase long- or short-term posttransplant mortality.[94]

Summary

HH may complicate the clinical course of a patient with cirrhosis. A high index of suspicion is needed to diagnose SBEM and to avoid the high mortality rate associated with this condition. Dietary sodium restriction and diuretic use are the mainstays of therapy for pleural effusion, but refractory patients may require therapeutic thoracentesis or TIPS for control. Ultimately, liver transplantation is curative for refractory HH.

PULMONARY COMPLICATIONS OF GASTROINTESTINAL DISEASE

In addition to the aforementioned pulmonary complications of liver disease, diseases of other intra-abdominal organs may have significant effects on the lungs. These include disorders of the esophagus, bowel, and pancreas. Pulmonary complications of renal disease are discussed separately, below.

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) affects up to 20% of the population.[95] GERD is characterized by reflux of gastric contents into the esophagus due to failure of the protective mechanisms of the upper gastrointestinal tract (see below) and produces symptoms of mucosal damage. In addition to the common symptom of "heartburn," reflux may be associated with a range of extraesophageal symptoms, including chronic cough, asthma, IPF, bronchiectasis, aspiration pneumonia, and COPD.[96]

Pathophysiology

Normally, several antireflux mechanisms protect the esophagus and airways from gastric contents: (1) Esophageal peristalsis allows clearance of regurgitated materials; dysmotility is associated with GERD. Abnormal peristalsis is reported in 40% to 50% of affected patients.[97] (2) The lower esophageal sphincter creates a barrier between the esophagus and the stomach. An incompetent lower esophageal sphincter is associated with reflux. (3) The diaphragm helps prevent reflux through external compression of the lower esophagus. Maintenance of a low thoracoabdominal pressure gradient may be important in minimizing reflux. Obese patients have higher incidence of GERD, which may be a reflection of the increase in intra-abdominal pressure that occurs with obesity.[98,99]

GERD-related pulmonary disease occurs with gross aspiration of large volumes of gastric contents, recurrent microaspiration, or, possibly, a GERD-induced reflex that causes an increase in vagal tone and resultant bronchospasm.[100,101]

Diagnosis

Diagnostic testing includes ambulatory esophageal pH monitoring and esophageal impedance testing.

Ambulatory Esophageal pH Monitoring Twenty-four hour ambulatory pH monitoring is considered the "gold-standard" diagnostic maneuver.[102] Until recently, this procedure required a catheter-based system, inserted through the nose and placed near the squamocolumnar junction in the esophagus. Various symptom scoring techniques allow linking of patient symptoms and reflux events to determine an association between the two and potential therapeutic intervention. However, the catheters employed are uncomfortable and external, and data suggest that the catheter itself may alter patient activity enough to impede the diagnostic accuracy. Recently, a capsule-based system with wireless data transmission has been developed, allowing increased patient comfort and incremental data collection to aid in the diagnosis of GERD. Currently, the American College of Gastroenterology recommends ambulatory pH monitoring for patients with negative findings on esophagogastroduodenoscopy who are being considered for an antireflux procedure, and for those failing therapy with a proton pump inhibitor. Symptom correlation during the procedure is recommended, although its diagnostic role is unproven for extraesophageal symptoms other than chest pain.[103]

Esophageal Impedance Testing Esophageal impedance testing measures changes in tissue resistance to electrical current generated in adjacent electrodes encompassed within an esophageal catheter assembly. The setup allows for identification of retrograde or antegrade food bolus movement along the esophagus. It does not differentiate between acidic, weakly acidic, or alkaline material; therefore, the technique is often combined with pH monitoring. Impedance testing is more sensitive than pH monitoring alone for detecting the presence of GERD, although it has not been validated for the evaluation of extraesophageal manifestations of GERD.

Clinical Features

Several potential pulmonary associations of underlying GERD should be considered, including asthma, IPF, and chronic cough.

GERD and Asthma The nature of the relationship between GERD and asthma is a subject of controversy, but GERD is common and present in 15% to 83% of asthmatics.[104–107] Several mechanisms by which acid reflux may be related to bronchoconstriction have been described in the literature. Acid reflux into the distal esophagus is postulated to cause bronchoconstriction through vagal stimulation, increased bronchial reactivity, and microaspiration.[108,109]

Declines in esophageal and tracheal pH coincide with reduced airflow, suggesting that microaspiration of gastric acid may lead to bronchoconstriction.[110] Interestingly, some studies have actually suggested the converse—that asthma exacerbations promote GERD by increasing the pleural–peritoneal pressure gradient by lowering pleural pressure,[111] by promoting lower esophageal sphincter relaxation,[112] or, perhaps, by a direct effect of bronchodilators on the lower esophageal sphincter.[113]

Asthma guidelines suggest that GERD be treated in asthmatics who have complaints of heartburn or frequent night-time symptoms. However, in a study of more than 400 patients with poorly controlled asthma who received a proton pump inhibitor, treatment had no effect on respiratory exacerbations compared with those who received placebo.[114] Proton pump inhibitor therapy is generally not indicated for patients with asthma and no GERD symptoms. Current guidelines suggest that treatment of GERD may improve asthma control, citing grade B evidence.[115] Lifestyle measures, such as weight loss and head of bed elevation, may be helpful.

GERD and Idiopathic Pulmonary Fibrosis Recently, a clinical association has been noted between GERD and IPF; the estimated prevalence of GERD in the IPF population is 90%. This association coincides with a recent shift in thought regarding the etiology of IPF, away from one of active inflammation, and toward one of alveolar injury and maladaptive repair, resulting in fibroblast proliferation and, ultimately, lung fibrosis.[116] A strong association between IPF and GERD has been documented in prior studies.[117] In addition, one retrospective review of 14 patients awaiting lung transplantation for IPF-reported stabilization, but not improvement, of lung function with laparoscopic Nissen fundoplication, but a small phase 2 study of fundoplication did not find significant clinical improvement.[118,119] The mechanistic relationship between IPF and GERD, the best diagnostic modality for assessment, and the optimal treatment are areas of active investigation. Based on the available data, the most recent IPF management guidelines recommended regular antiacid treatment in patients with IPF.[118]

GERD and Chronic Cough GERD is a well-known cause of chronic cough, and treatment of GERD is considered a mainstay in initial therapy for chronic cough. GERD was identified as a cause of chronic cough in 1981, and since then data have emerged ranking it as the second most common cause.[120,121] Twenty-eight percent of patients with chronic cough that improves with GERD therapy deny typical symptoms of GERD.[122] Although 24-h esophageal pH monitoring is considered the most sensitive test for GERD in chronic cough, it is expensive and has limitations. Therefore, the American College of Chest Physicians guidelines on the treatment of cough recommend empiric therapy for GERD in patients with GERD symptoms whose cough is likely related to reflux.[123] Recommended treatment includes a combination of weight loss in overweight or obese patients, head of bed elevation, and avoidance of meals within 3 h of bedtime and medical therapy.[123]

Treatment

The three main treatments for GERD are antacids, histamine-2 receptor antagonists, and proton pump inhibitors. Proton pump inhibitors have established efficacy over other options and are now the mainstay of therapy. Surgical therapy using Nissen fundoplication is reserved for refractory cases; it may be performed through an open incision or laparoscopically. Finally, new, less invasive procedures to improve the function of the lower esophageal sphincter are under investigation.

Summary

GERD is a common condition, affecting up to 20% of the population. The reflux of gastric contents into the esophagus may exacerbate pulmonary conditions such as IPF, asthma, and COPD, but neither a causal relationship nor a significant response to therapy has been documented in these conditions. GERD is a frequent cause of chronic cough; treatment with a PPI may ameliorate symptoms in affected patients.

■ Inflammatory Bowel Disease

Pulmonary complications associated with inflammatory bowel disease (IBD) were first described in 1976 in a small series of patients who had both IBD and chronic bronchitis.[124] Since that time, a connection between IBD and pulmonary disease has been increasingly recognized, but the pathophysiology of the relationship remains unclear. Both Crohn's disease and ulcerative colitis have been associated with a variety of respiratory problems: airway disease, parenchymal lung disease, serositis, and pulmonary vascular disease.

Airway involvement, the most common pulmonary disorder in IBD, may present as bronchiectasis, chronic bronchitis, tracheitis, subglottic stenosis, or, rarely, small airway disease.[125,126] Pulmonary parenchymal involvement is less common, but cryptogenic organizing pneumonia, eosinophilic pneumonia, granulomatous lung disease, nonspecific interstitial pneumonitis, necrobiotic nodules, and sarcoidosis have been described in IBD.[125,127,128] The association between the gastrointestinal and pulmonary "inflammation" is unclear, but the majority of these pulmonary complications appear to be steroid-responsive.[127] Finally, patients with IBD have a twofold higher incidence of thromboembolic events than do age-matched controls; the risk of pulmonary embolism does not appear to be related to disease activity.[129]

PULMONARY COMPLICATIONS OF ACUTE PANCREATITIS

Acute pancreatitis is an acute inflammation of the pancreas, which may cause both systemic inflammatory response syndrome and multisystem organ dysfunction syndrome (Chapter 142). When multisystem organ dysfunction accompanies pancreatitis, mortality is reported at 15% to 20%.[130,131] Pulmonary complications of pancreatitis are reported in 75% of cases. The most common presentations are hypoxemia without radiologic abnormalities, pleural effusions, or, in the sickest patients, acute respiratory distress syndrome (ARDS).[132,133]

■ Hypoxemia

Hypoxemia occurring early in the course of pancreatitis, even prior to development of radiologic abnormalities, is well documented and a risk factor for ARDS and increased mortality.[132,134,135] Early hypoxemia is an independent predictor of poor outcome and is included in the pancreatitis severity scores of both Ranson and Imrie.[136,137]

Several inflammatory mechanisms are implicated in development of the early lung injury of pancreatitis. Increased permeability at the microvasculature leads to alveolar filling and decreased lung compliance. In addition, nitric oxide–related endothelial cell damage occurs, with leukocyte activation and adhesion at the level of the pulmonary microvasculature. Furthermore, the systemic release of pancreatic elastase may contribute to inflammation in the lung parenchyma, and fibrinogen metabolism may allow fibrin deposition in alveoli. Collectively, these processes transform the relatively benign environment of the alveolus into an inflammatory milieu and profoundly affect gas exchange.

■ Pleural Effusion

The presence of a pleural effusion is a marker of pancreatitis severity and occurs in 84% of patients with severe disease, but only 8.6% of patients with mild disease.[143] The presence of a pleural effusion in acute pancreatitis is associated with increased in-hospital mortality.[138] Approximately two-thirds of the effusions are left sided, but they may be bilateral or right sided.[139] The effusion is usually small and may be hemorrhagic. Analysis of pleural fluid reveals a very high amylase and elevations in protein and lactate dehydrogenase levels when compared with serum.[140] Pleural effusions in acute pancreatitis may be caused by transdiaphragmatic lymphatic blockage or arise as a sympathetic effusion due to associated inflammation. A rare complication is a pancreaticopleural fistula, in which the pancreatic duct or a pseudocyst empties posteriorly into the retroperitoneum, tracking up the mediastinum and rupturing into the pleural cavity. The resulting effusions are generally massive and require evacuation and correction of the anatomic defect.[141,142] When less than massive, the effusions are treated conservatively and typically resolve with resolution of the pancreatitis.

■ Acute Respiratory Distress Syndrome

ARDS develops in approximately 15% to 20% of patients with acute pancreatitis. When present, mortality rises >50%.[143] The pathophysiologic basis of ARDS in acute pancreatitis is poorly understood, but inflammatory cytokines have been implicated (Chapter 140). Specifically, trypsin injures the pulmonary vasculature and promotes leukostasis and increased vascular permeability.[144,145] Phospholipase A2 (PLA2), which removes fatty acids from phospholipids, may act on surfactant, contributing to respiratory failure.[146,147] Multiple other mediators have been implicated, including IL-6, IL-8, NO, TNF-α, and substance P. Whatever the underlying mechanism, ARDS is the basis for 50% to 90% of deaths in acute pancreatitis.[148] Treatment is supportive and incorporates an alveolar protective ventilator strategy (Chapter 141).

Summary

Acute pancreatitis may cause a systemic inflammatory response syndrome or multisystemic organ dysfunction. One of the early signs of ensuing multisystem organ dysfunction may be hypoxemia, which is a risk factor for the later development of ARDS and early mortality. Pancreatitis is often accompanied by a pleural effusion, which is exudative and characterized by a high amylase level. In general, these effusions may be handled conservatively. ARDS occurs in 15% to 20% of patients with pancreatitis and is the cause of death in most who do not survive the bout of pancreatitis.

PULMONARY COMPLICATIONS OF RENAL FAILURE

Several notable associations exist between respiratory disease and renal failure, including PH and metastatic pulmonary calcification.

■ Pulmonary Hypertension and Renal Failure

PH associated with chronic kidney disease (CKD) is encompassed within group 5 of the World Health Organization classification of PH (PH with unclear or multifactorial causes).[11,149] CKD is defined by a reduced glomerular filtration rate (GFR) <60 mL/min/1.73 m^2 for ≥3 months. Screening for PH in CKD is accomplished using transthoracic echocardiography and estimation of right ventricular systolic pressure. Generally, a right ventricular systolic pressure >35 mm Hg is considered "abnormal" in patients with CKD.[149] Subsequent to screening, accurate characterization and definitive diagnosis of PH in CKD requires right heart catheterization. Patients with CKD are complex with respect to the many factors, acting individually or in combination, that may contribute to PH (Table 97-3).[150,151]

The frequency of PH in CKD has been reviewed extensively; findings depend on the stage of CKD, dialysis methods and duration, and method of assessment for PH (i.e., noninvasive transthoracic

TABLE 97-3 Common Hemodynamic Profiles in Patients with Chronic Kidney Disease (CKD)

CKD Associated Condition	mPAP	CO	PCWP	PVR
Chronic volume overload	↑	N	↑↑	N
Anemia	↑	↑	N	N
Increased cardiac output due to AV fistula	↑	↑	N	↓N
Left ventricular dysfunction (usually diastolic)	↑	N	↑	N↑

mPAP, mean pulmonary artery pressure (normal, <21 mm Hg); CO, cardiac output (normal, 4–6 L/min); PCWP, pulmonary capillary wedge pressure (normal, ≤15 mm Hg); PVR, pulmonary vascular resistance (normal, <3 Wood units: [MPAP–PWCP]/CO); N, normal.

echocardiography vs. right heart catheterization).[149,151] The incidence of PH in CKD varies from 9% to 39% in non-dialysis-dependent patients and up to 82% for those on hemodialysis. Patients undergoing peritoneal dialysis appear to have a lower incidence of PH than do patients on hemodialysis.[152] Precapillary PH (increased MPAP, normal PCWP, increased PVR) complicating CKD is present in approximately 25% of patients undergoing invasive hemodynamic evaluation, suggesting some patients may have intrinsic pulmonary vascular disease.[153] Often, other comorbidities such as COPD or sleep apnea exist and may contribute to PH as well.

The finding of PH on TTE in dialysis patients has ranged from 29% to 47% and is associated with increased all-cause mortality.[154,155] Conversely, CKD is common among patients with PAH and also associated with worse survival.[16] In a study of kidney transplant candidates, pretransplant severity of PH correlated significantly with worse posttransplant survival.[156] Echocardiographic PH has also been associated with posttransplantation allograft failure.[157]

The pathogenesis of PH in the setting of CKD is not well understood but may be related to endothelial dysfunction, alterations in nitric oxide signaling, and elevations in circulating vasoconstrictors, such as endothelin 1 and angiotensin II.[158]

Summary

The pathogenesis of, and optimal treatment regimen for, PH in CKD is poorly understood. The presence of PH is associated with a poor outcome in patients on dialysis and in those who undergo renal transplantation.

■ Metastatic Pulmonary Calcification

Metastatic calcification in the lung is a well-documented complication of CKD that requires hemodialysis. It is fairly common and present in 60% to 75% of autopsy specimens of patients on hemodialysis.[159,160] Despite this common pathologic finding, patients are generally asymptomatic, and only a minority have disease visible on the chest radiograph.[159]

Metastatic calcification in patients with CKD is thought to arise from several mechanisms. Chronic metabolic acidosis from renal failure leaches calcium and phosphate from bone. In addition, when bicarbonate is used for hemodialysis, a transient alkalosis may predispose to calcium deposition in tissue.[160,161] Secondary hyperparathyroidism, which is common in CKD, results in increased calcium and phosphate release from bone. Finally, decreased clearance of phosphate due to CKD results in an increased calcium-phosphate product and further salt deposition.[162] Deposition of calcium phosphate, the primary salt, is generally benign. However, the radiographic finding may result in a workup for pulmonary infiltrates. In difficult cases, differentiating metastatic calcification from pneumonia or edema is most definitively done using ^{99m}Tc-MDP bone scintigraphy, which identifies a calcified focus in the lungs.[163] Treatment is centered on lowering the patient's calcium-phosphate product with medication and dialysis. Although the majority of cases are benign in course, some are associated with progressive dyspnea, restrictive physiology, low diffusing capacity, hypoxemia, respiratory failure, and death.[164,165]

CONCLUSIONS

Intra-abdominal pathology may have distant effects on the pulmonary vasculature, pulmonary parenchyma, or pleural space. This chapter has provided a comprehensive overview of various pulmonary complications of intra-abdominal disease. Liver disease is associated with pulmonary vascular disorders, such as POPH and HPS, two conditions that impact liver transplant eligibility and prioritization, as well as pleural disorders such as HH and SBEM. GERD may exacerbate conditions such as asthma and IPF and has been associated with chronic cough, while IBD has been associated with varied pulmonary conditions, including airways disease, parenchymal disease, and an increased risk of thromboembolic disease. Acute pancreatitis can lead to multiorgan system dysfunction, hypoxemia, pleural effusions, and ARDS. Both PH and metastatic pulmonary calcification can occur in the setting of renal failure, and the presence of PH in CKD is associated with impaired survival. This chapter highlights the importance of recognizing the diverse pulmonary complications of intra-abdominal disease.

Sleep Apnea Syndromes: Central and Obstructive

Grace W. Pien
Ilene M. Rosen
Barry G. Fields

HISTORY OF SLEEP-DISORDERED BREATHING

Sleep-disordered breathing (SDB) is an extremely common disorder associated with significant morbidity. Recognition of its relevance in medicine is relatively recent, although clinical reports of SDB were first made in the 19th century.[1] Likely influenced by such observations, descriptions of an entity constituting obesity and extreme somnolence were highlighted in the character narrative of Joe in Charles Dickens's series *Posthumous Papers of the Pickwick Club,* first published in 1837.[2] Dickens described Joe as a loud snorer who was obese and excessively somnolent—the classic description of Pickwickian syndrome. Sir William Osler in 1918 was credited with first linking the relationship between obesity and Pickwickian syndrome.[3] In the mid-20th century, further work led to the association of Pickwickian syndrome with alveolar hypoventilation by Burwell et al. in 1956, and periodic cessation of respiration by Drachman and Gumnit in 1962.[4,5]

Over the last 40 years, we have begun to understand the pathogenesis of sleep apnea and have developed effective diagnostic and treatment modalities for this common disorder. Gastaut et al.[6] in 1965 showed that cessation of respiration was due to obstruction of the upper airway, and obstructive sleep apnea (OSA) was recognized. In 1972, a conference organized by Lugaresi and his Bologna (Italy) group, entitled "Hypersomnia and Periodic Breathing," served as a springboard for the growth of interest and research in SDB.[7] Guilleminault et al.[8] coined the terms *sleep apnea syndrome* and *obstructive sleep apnea syndrome (OSAS)* in 1976 to underscore that airway obstruction during sleep was not restricted to obese subjects.

As the understanding of the etiology of OSA increased, treatment options began to emerge. In 1969, a case report describing treatment of OSA in a patient with tracheostomy was published.[9] The first reports demonstrating reversal of OSA with positive airway pressure (PAP) did not occur until more than 10 years later.[10,11] The role of weight loss and its shortcomings in resolution of OSA were noted by Fishman in 1972.[12]

SLEEP APNEA DEFINITIONS

Adult SDB is present when repetitive apneas (episodes of near or total breathing cessation) and hypopneas (episodes of decrement in airflow) occur during sleep, usually associated with sleep fragmentation, arousals, and/or reductions in oxygen saturation. The most recent American Academy of Sleep Medicine (AASM) Scoring Manual[13] defines an apnea as a drop in the peak respiratory signal (using an oronasal thermal sensor, PAP flow, or alternative sensor) of ≥90% from baseline; in addition, the drop must be ≥10 s in duration.

Apneas should be classified as obstructive (in which there is no airflow despite continued respiratory effort), central (no airflow and no respiratory effort), or mixed (events initially appear central in origin, with respiratory effort occurring during the latter portion of the same episode). Notably, neither an oxygen desaturation nor an arousal is required to identify an apnea.

On the other hand, desaturations and arousals *are* generally necessary to define hypopneas. In the past, hypopnea definitions varied substantially according to the degree of airflow limitation expected, the magnitude of oxygen desaturation needed, and by whether the definition included events associated with an arousal but not oxygen desaturation.[14,15] The AASM Scoring Manual[13] currently defines a hypopnea as a drop in the peak respiratory signal (using an oronasal thermal sensor, PAP flow, or alternative sensor) of ≥30% from baseline; the drop must be ≥10 s in duration, *and* there is a ≥3% (option: ≥4%) oxygen desaturation from baseline, *or* the event is associated with an arousal from sleep apparent on the electroencephalogram (EEG).

The option to invoke a 4% desaturation instead of a 3% desaturation in the hypopnea definition impacts reported disease prevalence significantly.[16,17] Although both physiologic and epidemiologic studies have demonstrated that hypopneas produce the same clinical consequences as apneas, evolving hypopnea definitions can make it challenging to compare sleep apnea severity and associated consequences across different study populations.[18] Delineating obstructive (no airflow despite continued respiratory effort) and central (no airflow and no respiratory effort) hypopneas remains optional. In addition, the term *respiratory effort–related arousal (RERA)* is sometimes used to designate a series of breaths characterized by increasing effort leading to an arousal from sleep that does not meet the criteria for apnea or hypopnea.[19]

Currently, the apnea–hypopnea index (AHI, number of apneas and hypopneas per hour of sleep) is the standard metric used to describe the severity of sleep apnea.[13] In older papers, the term *respiratory disturbance index (RDI)* was often used interchangeably with AHI. More recently, some authors have included the number of RERAs per hour of sleep in the RDI definition, that is, number of apneas, hypopneas, and RERAs per hour of sleep. Nevertheless, neither AHI nor RDI take into consideration other characteristics of SDB such as the magnitude of oxygen desaturation or duration of hypoxia. There is recent evidence that these parameters can be better predictors of cardiovascular disease than AHI/RDI.[20] Azarbarzin et al. evaluated the association of "hypoxic burden" with increased cardiovascular disease (CVD) mortality in 7854 adults age 40 and older.[21] Hypoxic burden was defined as the area under the desaturation curve from pre-event baseline during respiratory events. The authors found that elevated hypoxic burden significantly predicted CVD mortality in a dose–response manner, and it was a stronger predictor of CVD mortality than was AHI.

The respiratory event index (REI) is another metric of OSA severity being used more commonly. This terminology was introduced to differentiate respiratory indices obtained from in-laboratory polysomnography (PSG) with those derived from home sleep apnea testing (HSAT). The REI is the total number of apneas and hypopneas per hour of monitoring time[13] since, unlike PSG-defined AHI, total sleep time is only estimated using HSAT. Although more studies are using REI as a primary determinant of OSA presence and severity,[22] there is concern for OSA severity bring underestimated,[23] since total sleep time is overestimated.

■ Obstructive Sleep Apnea

OSA is defined by the presence of repetitive episodes of upper airway obstruction during sleep. An AHI of at least 5 events/h is commonly used to define OSA, with obstructive or mixed (rather than central) events accounting for more than 50% of the total.[13] OSAS is usually defined by an AHI of at least 5 events/h and persistent complaints of excessive daytime somnolence, unrefreshing sleep, or fatigue.[24] Other OSA definitions suggest that OSA be diagnosed if the AHI is at least 10 to 14 events/h, or in cases in which the AHI is between 5 and 14 events/h and documented hypertension, ischemic heart disease, history of stroke, or symptoms of excessive daytime sleepiness, impaired cognition, mood disorders, or insomnia exist.[25,26]

OSA is often classified as mild, moderate, or severe according to the AHI. A common scheme is 5 to <15 (mild), ≥ 15 to ≤ 30 (moderate), >30 events/h (severe).[27] These definitions were based on expert consensus. Some authors have suggested that severity should be defined by associations with adverse clinical outcomes rather than the event index.[28,29] Changes in clinical hypopnea definitions by organizing bodies such as the American Academy of Sleep Medicine (AASM) have also provoked debate over parameters of disease severity.[13,17,30]

In the past, the term *upper airway resistance syndrome (UARS)* has been used to describe symptoms of sleepiness and fatigue in the setting of milder SDB not meeting criteria for apneas and hypopneas.[31] Advances in detection of SDB events (e.g., with nasal pressure) and the inclusion of events associated with arousals in the hypopnea definition have likely eliminated the need to designate UARS as a separate entity.[15,32] These individuals are now likely to be diagnosed with OSA. Debate continues as to whether some nonobese individuals may have a hypersensitive arousal response to repetitive increased respiratory effort that is distinct from OSA.[33–35]

■ Central Sleep Apnea

Central sleep apnea (CSA) is much less common than OSA and is characterized by a transient cessation of rhythmic breathing. It is defined as repeated episodes of apnea in the absence of respiratory muscle effort and is observed on the polysomnogram as an absence of both nasal–oral airflow and thoracoabdominal excursion.[36] A number of etiologies for CSA have been recognized, among which congestive heart failure (CHF) and stroke are the most common.[37–39] Patients with CSA experience sleep fragmentation and can report similar daytime symptoms to those with OSA.

■ Obesity Hypoventilation Syndrome

Obesity hypoventilation syndrome (OHS), or the Pickwickian syndrome, is defined by obesity (BMI ≥ 30 kg/m^2) and hypoventilation with daytime hypercapnia in the absence of other causes for hypoventilation.[24] Thus, OHS should be regarded as a diagnosis of exclusion. Notably, while 90% of patients with OHS have been estimated to have OSA, the presence of OSA is *not* necessary for the diagnosis of OHS.[40,41] Conversely, 10% to 15% of sleep apnea patients have been noted to have daytime hypercapnia and can be classified as having concomitant OHS.[42] OHS is discussed more fully in Chapter 99.

PATHOGENESIS OF OBSTRUCTIVE SLEEP APNEA

The pathogenesis of OSA involves both anatomic and neurologic components. The upper airway is a complicated structure that performs multiple physiologic functions, including vocalization, respiration, and deglutition. The upper airway extends from the posterior margin of the nasal septum to the larynx and has a paucity of rigid bony support. It is divided into four anatomic regions (Fig. 98-1): the *nasopharynx*—the region between the nares and the hard palate; the *retropalatal oropharynx*—the region between the hard palate and the caudal margin of the soft palate; the *retroglossal oropharynx*—the region between the caudal margin of the soft palate and the base of the epiglottis; and the *hypopharynx*—the region from the base of the tongue to the larynx.

The major contributors to the airway boundaries include the soft palate and tongue anteriorly; the pharyngeal constrictor muscles, lymphoid tissue, parapharyngeal fat pads, and mandibular rami laterally; and the pharyngeal constrictor muscles posteriorly.[43,44] The soft tissue and craniofacial (bony) structures in the retropalatal and retroglossal regions contribute to the specific morphology of the airway of a given individual.[44] Collapse of the upper airway reduces its airway intraluminal diameter and increases airway resistance, leading to the apneas and hypopneas that characterize OSA.[45,46] Figure 98-1 displays a midsagittal magnetic resonance image in a normal individual in which the retropalatal and retroglossal regions are outlined. This midsagittal image also highlights the airway, tongue, soft palate, mandible, and subcutaneous fat. The lateral upper airway soft tissue structures of the retropalatal region (that is, the lateral pharyngeal walls and lateral parapharyngeal fat pads) are depicted in Fig. 98-2.

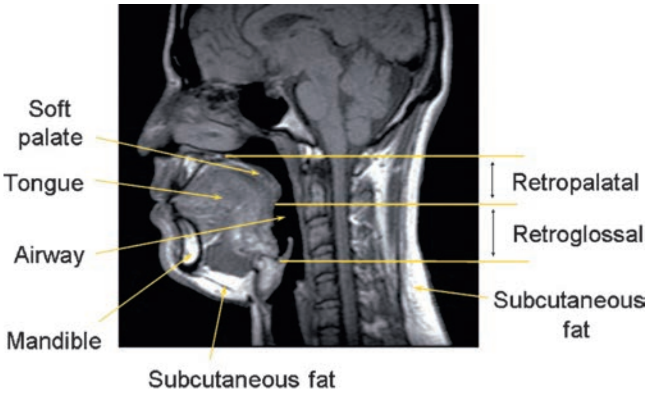

Figure 98-1 Midsagittal magnetic resonance (MR) image in a normal individual demonstrating the anatomic regions of the upper airway and relevant craniofacial and soft tissue structures. The retropalatal (RP) region is defined from the level of the hard palate to the distal margin of the soft palate; the retroglossal (RG) region is defined from the distal margin of the soft palate to the base of the epiglottis. In patients with OSA, obstruction usually occurs in the retropalatal or retroglossal levels or at both locations. *(Reproduced with permission from Schwab RJ, Gupta KB, Gefter WB, et al. Upper airway and soft tissue anatomy in normal subjects and patients with sleep-disordered breathing. Significance of the lateral pharyngeal walls. Am J Respir Crit Care Med. 1995;152(5 Pt 1):1673–1689.)*

Anatomic factors are clearly a major contributor to the propensity for airway collapse during sleep. In addition, the critical role of neuromechanical control of the upper airway in the pathophysiology of OSA is becoming increasingly well understood.

■ Anatomic Features That Predispose to Obstructive Sleep Apnea

The extrathoracic upper airway lacks a robust support framework of cartilaginous rings and therefore is at risk for collapse due to extraluminal tissue pressure exerted by circumferential craniofacial and soft tissue structures and negative pressure associated with inspiration. Changes in pharyngeal transmural pressure, defined as the difference between the pressure in the airway lumen and the pressure exerted by tissues surrounding the site of collapse, modulate upper airway size. Activity of the pharyngeal dilator muscles offsets extraluminal tissue pressure to help maintain upper airway patency.[47]

Among individuals with sleep apnea, upper airway collapse occurs most commonly in the retropalatal and retroglossal regions, reducing airway intraluminal diameter and increasing airway resistance, which leads to apneas and hypopneas.[48] Multiple sites of potential upper airway collapse have been visualized in patients with OSA and tend to be reproducible from episode to episode.[49] During

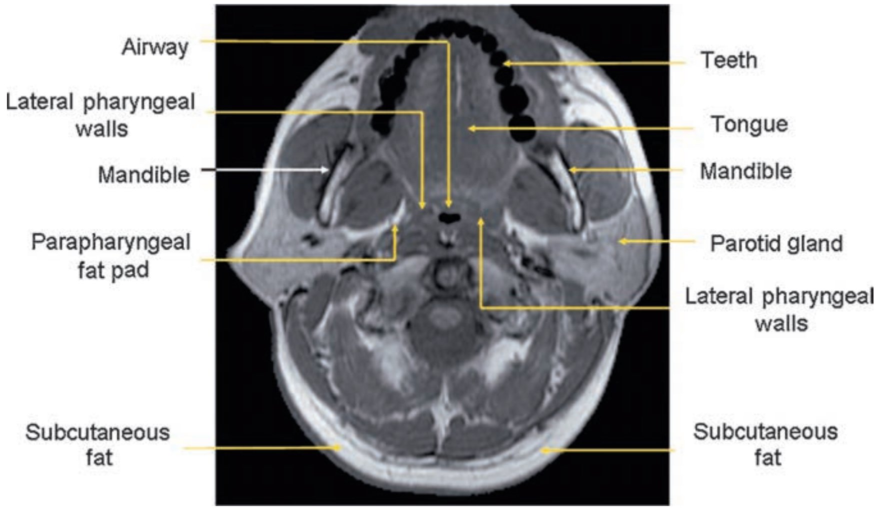

Figure 98-2 Axial magnetic resonance (MR) image at the retropalatal level in a normal subject. The relevant soft tissue and bony structures surrounding the upper airway are highlighted. The tissues immediately lateral to the airway are the lateral pharyngeal walls and the parapharyngeal fat pads. *(Reproduced with permission from Schwab RJ, Gupta KB, Gefter WB, et al. Upper airway and soft tissue anatomy in normal subjects and patients with sleep-disordered breathing. Significance of the lateral pharyngeal walls. Am J Respir Crit Care Med. 1995;152(5 Pt 1):1673–1689.)*

wakefulness, upper airway caliber is smaller in patients with sleep apnea compared with normal individuals.[50] Habitual snorers also have generalized narrowing of the pharyngeal lumen compared with normal subjects, regardless of whether they are obese.[44] Nevertheless, smaller upper airway caliber does not entirely explain OSA risk: men have larger pharyngeal airway cross-sectional area and airway volumes than women but are more likely to develop sleep apnea. Differences in airway length have been proposed to explain gender disparity in OSA risk, given observations that men have longer, and thus more collapsible, pharyngeal airways compared with women.[51] A reduction in the lateral diameter of the airway in individuals with OSA, with relative preservation of the anterior–posterior diameter, also may promote upper airway dysfunction.[52]

In population studies, neck circumference is a strong predictor of OSA.[53] Consistent with this observation, individuals with OSA demonstrate an excess of upper airway soft tissue for the space within the craniofacial structures that envelop the pharyngeal lumen. Patients with sleep apnea have larger tongues and longer soft palates than normal subjects (Fig. 98-3).[51,54–56] The larger the volume of the lateral pharyngeal walls, tongue, and total upper airway soft tissue (Fig. 98-4), the greater the likelihood of having OSA; specifically, increased thickness of the lateral pharyngeal walls may contribute to narrowing of the apneic airway.[54]

Imaging studies have demonstrated that the total volume of fat surrounding the airway is also greater in apneic individuals compared with BMI-matched normal subjects.[57] Recent evidence has highlighted the importance of tongue fat in the development of OSA. The initial identification of the role of tongue fat came from studies in mice.[58] The New Zealand Obese (NZO) mouse, which has a polygenetic abnormality that leads to morbid obesity and diabetes,[59,60] has been demonstrated to sleep upright, presumably to protect the upper airway from collapse. Imaging studies revealed a narrowed upper airway in the NZO mice with an increased tongue size compared to wild-type mice. Histologic examination revealed fat infiltration in the tongue.[58] These studies in mice have been extended to humans. In case-control analyses using Dixon imaging with MRI, individuals with OSA have more tongue fat than controls after controlling for differences in BMI (Fig. 98-5).[61]

These findings suggest that fat deposition in the neck—in the parapharyngeal fat pads, under the mandible, and particularly in the tongue—reduces upper airway caliber.[61] Increased soft tissue mass may increase tissue pressure, resulting in airway collapse and decreased airway volume.[47]

Variations in craniofacial morphology also influence upper airway configuration. For example, maxillary deficiency, mandibular retrusion, increased hyoid–mandibular plane distance, and abnormalities of the cranial base have all been associated with higher risks of sleep apnea.[62–66] The heritability of craniofacial structures associated with OSA has been demonstrated in a study examining individuals with sleep apnea and their siblings, and comparing them to controls without

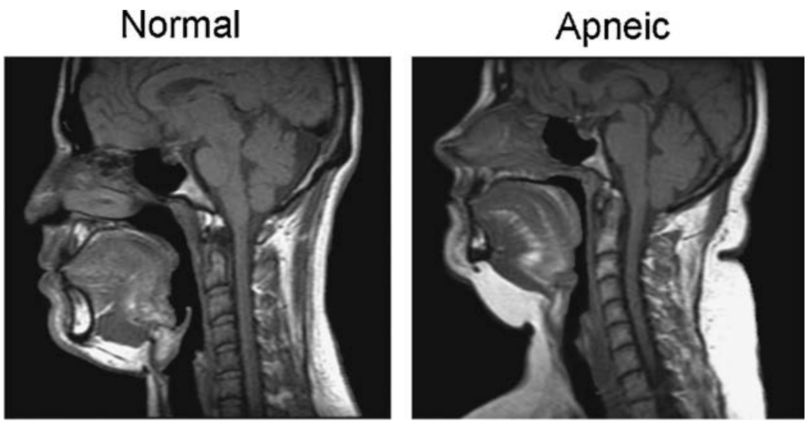

Figure 98-3 Midsagittal magnetic resonance imaging (MRI) of a normal subject on the left and a patient with sleep apnea on the right. The upper airway is smaller in both the retropalatal and retroglossal region in the apneic patient. The soft palate is longer in the apneic patient. The tongue is bigger in the retroglossal region in the patient with sleep apnea. The amount of subcutaneous fat (white area at the back of the neck) is greater in the apneic. *(Reproduced with permission from Schwab RJ, Gupta KB, Gefter WB, et al. The reconstruction is from series of 3-mm contiguous axial MR images superimposed on midsagittal images. The apneic tongue on the left is significantly larger with increased tongue fat compared to the non-apenic tongue on the right. Subjects were matched for age, gender, menopausal status, and ethnicity. *(Reproduced with permission from Kim AM, Keenan BT, Jackson N, et al. Tongue fat and its relationship to obstructive sleep apnea. Sleep. 2014;37(10):1639–1648.)*

OSA and their siblings.[67] Craniofacial abnormalities are more likely to be observed among nonobese persons with OSA, whereas obese individuals with OSA are more likely to have larger soft tissue structures.[42,68]

Changes in upper airway anatomy during the respiratory cycle can influence the propensity for airway collapse during both inspiration and expiration. Using dynamic upper airway imaging with CT, MRI, and nasopharyngoscopy, the airway's geometric changes have been partitioned into three phases (Fig. 98-6). During inspiration, upper airway area is relatively constant, implying a balance between muscle dilator activity and negative airway lumen pressure. In early expiration, the activity of airway dilator muscles decreases, intraluminal pressure rises, and the airway widens maximally. At end expiration, upper airway dimensions decrease. Patients with OSA have more narrowing during end expiration compared to normal controls.[52,69,70] Drug-induced sleep endoscopy (DISE), during which pharmacologic agents are used to induce a level of sedation approximating natural sleep, provides a three-dimensional evaluation of the likely site of upper airway collapse in patients with OSA.[71] During the DISE procedure, a flexible laryngoscope is used to assess the entire length of the pharynx across several cycles of airway obstruction and normal breathing. Various classification schemes such as the widely used VOTE Classification (Velum, Oropharyngeal lateral walls, Tongue, Epiglottis) are used to identify structures that contribute to pharyngeal obstruction and the degree of airway narrowing associated with each structure. Identification of the site of airway obstruction during DISE can guide the use of therapeutic alternatives to CPAP therapy[71] and is essential for determining whether patients are likely to benefit from hypoglossal nerve stimulation surgery for OSA.[72]

A number of studies have also demonstrated that redistribution of extracellular fluid from the legs to the upper body can occur during sleep and in the supine position, leading to significant increases in neck circumference and airway collapsibility, and a reduction in upper airway cross-sectional area.[73–75] The magnitude of fluid redistribution is associated with the degree of SDB, suggesting a contributory role for this mechanism in the development of OSA. However, absolute AHI fell only modestly in a small crossover study in which patients wore compression stockings during the daytime to reduce nocturnal fluid shifts, suggesting that this mechanism does not play a major role in OSA pathogenesis.[76]

■ Neural Modulation of Upper Airway Patency

During sleep, the balance in transpharyngeal pressure shifts toward upper airway collapse due to reduced upper airway dilator muscle activity. MR images suggest that even among normal individuals,

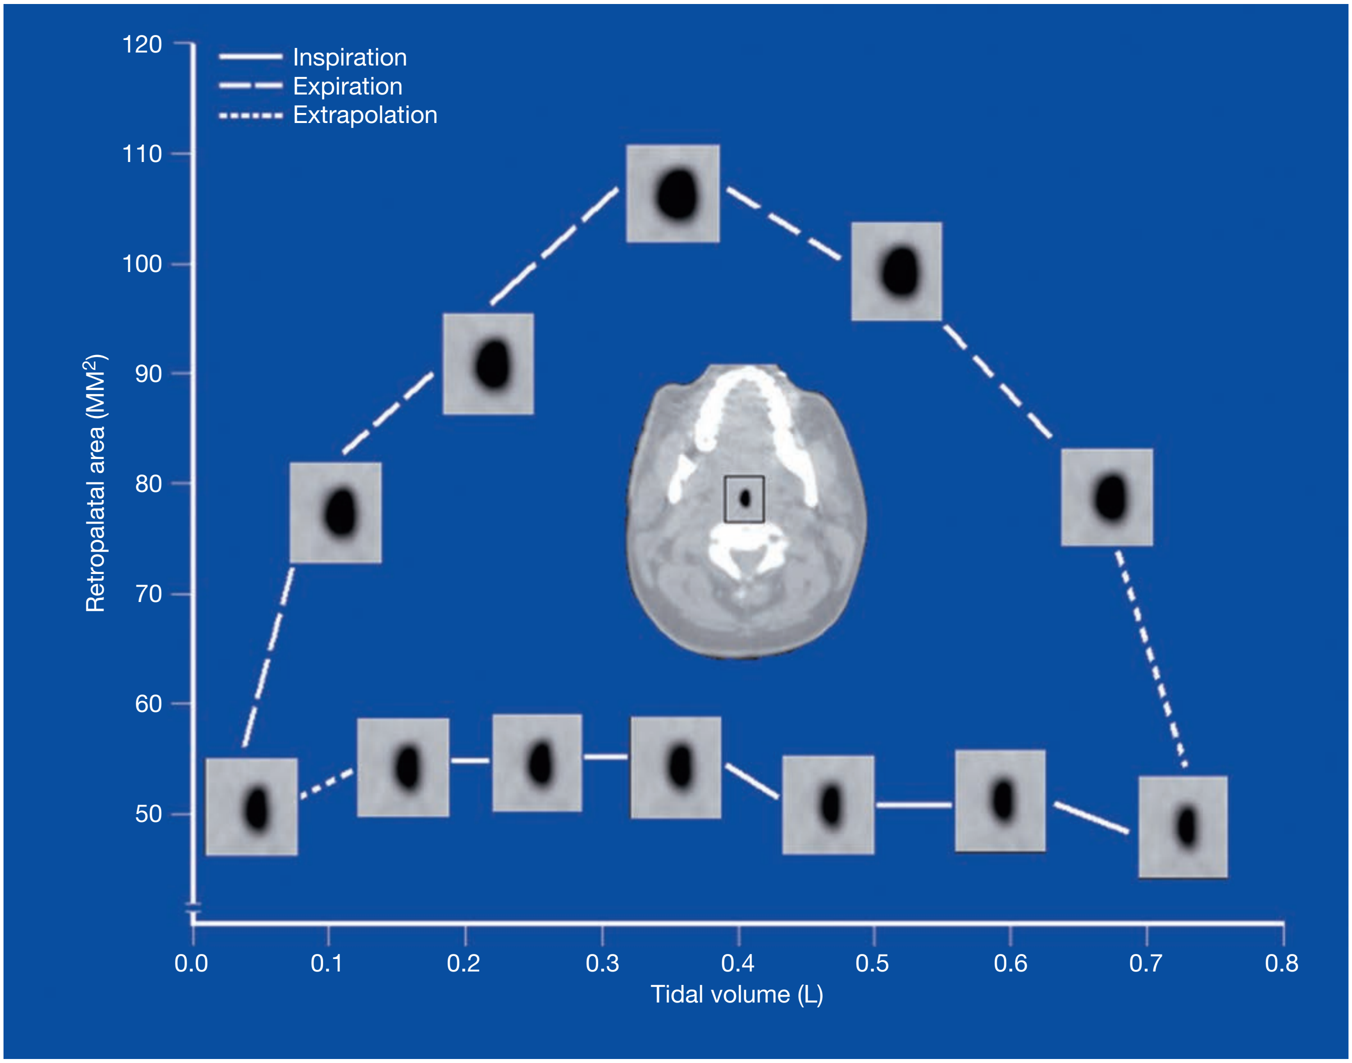

Figure 98-6 Changes in upper airway area as a function of tidal volume during the respiratory cycle using cine computed tomography (CT). Airway caliber is relatively constant in inspiration. Airway size increases in early expiration and decreases in late expiration. *(Reproduced with permission from Schwab RJ, Gefter WB, Hoffman EA, et al. Figure 98-7 Volumetric state–dependent airway imaging in a normal subject using magnetic resonance imaging (MRI). Airway volume during sleep is smaller in the retropalatal (RP) region but not the retroglossal (RG) region. Such images suggest that the upper airway during sleep does not narrow as a homogeneous tube. Nonetheless such images indicate that the upper airway of subjects without sleep apnea narrows during sleep. *(Reproduced with permission from Schwab RJ, Pasirstein M, Pierson R, et al. Identification of upper airway anatomic risk factors for obstructive sleep apnea with volumetric magnetic resonance imaging. Am J Respir Crit Care Med. 2003;168(5):522–530.)*

the retropalatal upper airway narrows during sleep (Fig. 98-7). The neural control of the upper airway muscles is complex and involves several neurotransmitters (serotonin, norepinephrine, orexin–acetylcholine, and gamma-aminobutyric acid) that are influenced by sleep itself.[77–79] The most widely studied upper airway muscle is the genioglossus.

Three neural mechanisms have been shown to be operative with regard to genioglossus muscle activity and vulnerability to obstructive apneic events. First, negative airway pressure detected by laryngeal mechanoreceptors activates the genioglossus via increased hypoglossal nerve discharge. This reflex is diminished during non-REM sleep compared with wakefulness, and it is further reduced during REM sleep, placing the airway at risk for collapse.[80–83] A state-sensitive motor inhibitory cholinergic channel that operates at the hypoglossal motor pool has been identified as the principal mechanism of REM sleep pharyngeal motor inhibition.[84] Furthermore, patients with OSA have reduced upper airway reflexes during sleep compared with normal individuals.[85] Whether these differences occur due to individual variability in neuromuscular responses, placing some individuals at increased risk for OSA, or whether repetitive injury from snoring vibration or oxidative stress leads to neural or muscular damage has been debated.[86–88]

Second, the upper airway muscles respond to input from the respiratory control center in the medulla, with increases and decreases in activity in proportion to respiratory drive. In situations of ventilatory control instability in which respiratory drive waxes and wanes, diminished upper airway muscle activity can precipitate airway collapse, that is, obstructive apnea.[89,90] Third, neural mechanisms modulating arousal (serotonergic and noradrenergic neurons) have a tonic excitatory influence on genioglossus activity. With the onset of sleep, there is a reduction in arousal-modulated excitatory output to the upper airway musculature.[91,92] During episodes of upper airway collapse, arousal from sleep in response to respiratory activation helps to restore airway patency.[93,94] Although arousals are not always necessary for recovery from upper airway obstruction, patients with OSA have a diminished ability to restore ventilation without cortical arousal compared with nonsnorers.[95]

■ The Apneic Event

Occlusion of the airway results in a range of immediate physiologic disturbances. Episodic reductions or cessations in ventilation despite continued respiratory efforts, recurrent episodes of intermittent hypoxemia, and frequent arousals from sleep form the basis for a cascade of downstream perturbations. During obstructive apneas, breathing efforts create abrupt reductions in intrathoracic pressure that can increase atrial natriuretic peptide (ANP) release and left ventricular (LV) transmural pressure, compromise LV filling, and increase both preload and afterload.[96–100] Myocardial oxygen demand increases despite reduced coronary blood flow and decreased oxygen delivery due to apnea-related hypoxia.[101] Surges in sympathetic nervous system activity that occur due to apnea, hypoxia, hypercapnia, and arousal result in increased peripheral resistance and cardiac stimulation, which in turn lead to postapneic increases in blood pressure (BP) and heart rate.[102–105] These elevations in sympathetic activity persist during the day in individuals with OSA.[106] Moreover, individuals with the largest magnitude of change in heart rate response to apneic events have been observed to be at increased risk of nonfatal or fatal cardiovascular disease and all-cause mortality.[107] This increased risk was accentuated among those with the highest hypoxic burden.

Intermittent hypoxemia is associated with increased production of reactive oxygen species and oxidative stress, which can impair endothelially mediated vasodilation, contributing to BP elevation.[108,109] Reactive oxygen species also increase activity of the transcription factor nuclear factor kappa B (NF-κβ), a key component of the inflammatory response.[110] NF-κβ stimulates the production of inflammatory mediators (e.g., C-reactive protein, tumor necrosis factor α, and interleukins 6 and 8) and adhesion molecules (platelet endothelial adhesion molecule, intercellular adhesion molecules [ICAMs]).[111–115] These effects of intermittent hypoxia are likely to promote endothelial damage and atherosclerosis.[116,117] Many of these studies have been performed in mice exposed to chronic intermittent hypoxia, in which the ambient oxygen concentration is lowered cyclically, for example, to 5% for 60 cycles/h for 8 h/day.[118] Several of these preclinical studies suggest that visceral adipose tissue is an important source of proinflammatory mediators in OSA,[118,119] although the impact of adipose tissue on vascular inflammation in OSA is not well defined.

Termination of obstructive apneas usually occurs with a transient arousal or awakening from sleep. Arousals are coupled with respiratory effort and involve both chemical (hypoxia) and mechanical (increased respiratory effort against an occluded airway) stimuli.[120,121] Arousal mechanisms can be adversely affected by alterations in chemosensitive systems, ingestion of alcohol, or use of sedatives and hypnotics, leading to prolongation of apneic events.[122,123]

EPIDEMIOLOGY AND RISK FACTORS FOR OSA

Below we consider the epidemiology of OSA and important underlying risk factors.

■ Epidemiology of OSA
